Abstract: The influence of the amorphisation technique on the physico-chemical properties of amorphous lactulose has been investigated. Four different amorphisation techniques have been used: quenching of the melt, milling, spray-drying and freeze-drying, and amorphous samples have been analysed by DSC, NMR, and powder X-ray diffraction. Special attention has been paid to the tautomeric composition and to the glass transition of amorphised materials. It has been found that the tautomeric composition of the starting physical state (crystal, liquid or solution) is preserved during the amorphisation process and has a strong repercussion on the glass transition of the material. The correlation between these two properties as well as the plasticizing effect of the different tautomers have been clarified by molecular dynamic simulations.

Keywords: mutarotation, amorphisation, milling, quenching melt, spray-drying, freeze-drying, molecular dynamics simulation, MDSC, NMR

1. Introduction

Glass forming sugars play a major role in nature as they are able to protect biological systems from many external stresses^{1,2}. They are in particular synthesised in large quantities by organisms which can resist to freezing, high temperatures and severe dehydrations²⁻⁴. Glass forming sugars are also widely used in pharmaceutical formulation^{5,6} for the encapsulation, the stabilisation, and the release of drugs^{7,8} and nutrients⁹. They help to preserve labile biological molecules like proteins from stresses induced by some usual pharmaceutical processes^{10,11} (freeze-drying, spray-drying, milling, extrusion, heating...).

Most sugars can exist in different tautomeric forms which can adopt cyclic or open chain conformations^{12,13}. This is, for instance, the case of glucose¹⁴, sorbose¹⁵, fructose¹⁶, lactose¹⁷ and many others. Mutarotation is another striking feature of sugars^{15,18-21} which is the conversion of one tautomeric form into another. The kinetic of this conversion strongly depends on the physical state of the material. In solution or in the liquid state, mutarotation is generally fast and an equilibrium tautomeric composition is rapidly reached. In the amorphous solid state, mutarotation has been found to require a much higher activation energy so that mutarotation kinetics are quite slower^{16,22-25}. While there is almost no molecular mobility in crystals, Tombari et al. have postulated that mutarotation can also occur in this ordered physical form through the mediation of vacancies and defects. It then causes local amorphisations which could ultimately lead to the liquefaction of sugars well below their reputed melting points²⁶. All these changes in the tautomeric composition due to mutarotation can have a strong repercussion on the physical properties of the material and in particular on its glass transition temperature (T_g). For instance, Włodarczyk et al.¹⁶ have shown that the T_g of tautomerically pure fructose (pyranose form) can change by 10°C when it converts to a mixture of pyranose and furanose forms by mutarotation. Such a change of the molecular mobility can thus have critical repercussion on the physical stability of glass forming sugars.

In practice, amorphous sugars can be produced by many different techniques which drive materials through different intermediate physical states²⁷. To cite only a few: i) the classical thermal quench of the melt involving the liquid state^{28,29}, ii) the mechanical route (compression, milling) occurring entirely in the solid state³⁰⁻³² iii) the solvent removal processes (freeze-drying³³, spray-drying³⁴...) requiring the dissolution of the drug in a solvent. These different processes are not yet fully understood and can possibly lead to different amorphous states characterised by different chemical and physical properties. In particular, the amorphisation process can generate impurities arising from chemical degradation, leave residual traces of solvent, and modify the tautomeric composition if molecules are prone to mutarotation. It can also have an impact on the enthalpic level, the short-range order and the microstructure of the amorphous state. All these parameters must thus be understood and controlled as they have a direct influence on the glass transition and the effective physical stability of the final product against recrystallisation.

In this paper, we investigate the influence of the amorphisation route on the physical and chemical states of amorphous lactulose³⁵. Four amorphisation routes were explored: quenching of the melt, milling of the crystal, spray-drying and freeze-drying. Physical and chemical properties of these samples were investigated by nuclear magnetic resonance

(NMR), differential scanning calorimetry (DSC) and X-ray diffraction (XRD). Lactulose was chosen for its excellent glass forming ability, its high solubility and its complex tautomerism made of five tautomers which can inter convert by mutarotation³⁶. Tautomers A (galactosyl β -furanose), B (galactosyl α -furanose) and C (galactosyl β -pyranose) were detected in large proportions. Their chemical structures are reported in Figure 1. On the contrary, tautomers D (galactosyl α -pyranose) and E (partially open-chain transiently produced during mutarotation) are much rarer and have not been detected in the present study.

Special attention has been paid here to the effect of the amorphisation process on the tautomeric compositions of the resulting amorphous state and to its repercussion on the glass transition temperature (T_g). The correlation between these two characters as well as the plasticizing effect of the different tautomers have been further investigated by molecular dynamic (MD) simulations.

Figure 1: Chemical structures of the three main disaccharide lactulose ($C_{12}H_{22}O_{11}$) tautomers A, B and C. There exists two other tautomers that appear only in the state of traces³⁶.

2. Experimental and simulations

2.1 Material

Crystalline anhydrous lactulose was purchased from Sigma Aldrich. Thermogravimetric experiments have shown that it contains about 3.5 % of water inclusions. The commercial form was thus slightly crushed to favour water release, and dried at 70 °C during 15 min. The obtained sample has been checked to be totally crystalline, and has been used for the different experiments.

2.2 Amorphisation methods

We used four different techniques to prepare amorphous lactulose compounds: quenching of the melt, milling, spray-drying and freeze-drying. The amorphous samples obtained using these techniques will be respectively noted QM, MIL, SD and FD in the following.

a- Quenching of the melt

Quenched melt was obtained by heating (5°C/min) crystalline lactulose just above its melting point ($T_m = 161^\circ\text{C}$) and by quenching (10°C/min) the melt at 20°C. The whole process was performed in the DSC device, under a nitrogen atmosphere and with a small sample size. This allows to control the melting process and to minimise the time spent above T_m in order to limit as much as possible thermal degradation³⁷.

b- Milling

Ball milling was performed during 8h in a cold room at -10°C and under a dry atmosphere (RH ~ 0%) using a high-energy planetary mill (Pulverisette 7—Fritsch, Idar-Oberstein, Germany). We used ZrO₂ milling jars of 43 cm³ with seven balls ($\phi = 15$ mm) of the same material. 1 g of material was placed in the milling jar corresponding to a ball/sample weight ratio of 75:1. The rotation speed of the solar disk was set to 400 rpm. We took care to alternate milling periods (typically 10 min) with pause periods (typically 5 min) in order to limit the mechanical heating of the sample. Lactulose was milled during 8h as this milling time was reported to be long enough to induce a complete amorphisation³⁷.

c- Spray-drying

Lactulose was dissolved in distilled water (5 g / 50 ml) at room temperature (RT) and spray-dried using a Buchi B-290 mini spray dryer (Buchi, Basel, Switzerland), equipped with a 0.7 mm nozzle (feed rate: 5 mL/min; air flow rate: 601 l/h; inlet temperature: 120°C± 2°C; outlet temperature: 70± 5°C; concurrent feed flow/inlet drying gas-nitrogen).

d- Freeze-drying

Lactulose was dissolved in distilled water (5 g / 50 ml) at RT and freeze-dried using the freeze dryer Christ Epsilon 2-4 LSC (Martin Christ, Osterode, Germany): freezing at $-45\text{ }^{\circ}\text{C}$ for 4 h, primary drying at $-20\text{ }^{\circ}\text{C}/0.007\text{ mbar}$ for 20 h, and secondary drying at $+35\text{ }^{\circ}\text{C}/0.0014\text{ mbar}$ for 40 h.

2.3 DSC experiments

Differential Scanning Calorimetry (DSC) was performed with the DSC Discovery of TA Instruments. For all experiments, the sample was placed in an open aluminum pan (container with no cover) to allow any residual free water to be removed upon heating, and was flushed with highly pure nitrogen gas. Temperature and enthalpy readings were calibrated using pure indium at the same scan rates and with the same kind of pans used in the experiments. Experiments were performed in the temperature modulated mode (MDSC) using a heating rate of $5\text{ }^{\circ}\text{C}/\text{min}$, a modulation amplitude of $0.663\text{ }^{\circ}\text{C}$ and a modulation period of 50 s. These parameters correspond to “heat only” conditions.

2.4 X-ray diffraction experiments

X-ray diffraction (XRD) experiments were performed with a PanAlytical X’PERT PRO MPD (Almelo, The Netherlands) diffractometer ($\lambda_{\text{CuK}\alpha} = 1.5418\text{ \AA}$ for combined $\text{K}\alpha_1$ and $\text{K}\alpha_2$) equipped with an X’celerator detector (Almelo, The Netherlands). Samples were placed into Lindemann glass capillaries ($\phi = 0.7\text{ mm}$). Data were recorded from 5° to $40^{\circ} 2\theta$ by step of $0.0167^{\circ} 2\theta$ using a counting time of 50 s every $2^{\circ} 2\theta$.

2.5 NMR experiments

NMR spectra were recorded with the NMR 400 MHz spectrometer commercialised by Bruker. 10 mg of sample were dissolved into 0.75ml of Dimethyl Sulfoxide (DMSO). We used this solvent for its ability to slowdown the mutarotation in solution strongly^{38,39}. The signal was collected at RT just after (typically 3 min) the dissolution, in order to limit as much as possible the mutarotation. For all experiments we used a 5 mm TBI probe which is suitable for proton NMR. Results were analysed using the TopSpin 3.5pl5 software of Bruker.

2.6 MD simulations

We have performed molecular dynamics (MD) simulations using the DLPOLY package⁴⁰ (version 4.07) and the OPLS (Optimised Potentials for Liquid Simulations) force field^{41,42}. We chose this force field due to its capability of reproducing successfully the experimental data for a large number of molecules with low molecular weight^{43–45}. We conducted the simulations either in the NPT or the NVT statistical ensemble, with N the number of molecules, P the pressure, T the temperature, and V the volume. The number of molecules, N , was fixed in the simulations. The pressure and temperature were controlled with a Nose-Hoover barostat and thermostat, with relaxation times of 2.0 ps and 0.2 ps respectively. We

performed all NPT simulations at atmospheric pressure and we used the equilibrated volume at a given P and T for subsequent NVT simulations. The time step to integrate Newton's equation of motion was chosen as 0.001 ps. A cut-off radius of 10 Å was used to calculate short-range van der Waals interactions. Long-range electrostatic forces were calculated using a shifted Coulombic potential, with the same cut-off radius. Periodic boundary conditions were applied in all directions.

In order to investigate the impact of the tautomeric composition on the molecular mobility of amorphous lactulose, we have calculated the diffusion coefficients of tautomers A and C, as well as their gyration radii R_g . The diffusion coefficient D is determined from the long-term evolution of the mean square displacement ($\langle r^2(t) \rangle \sim 6Dt$). The gyration radius R_g is determined thanks to the following equation:

$$R_g = \langle (\sum_{\alpha} m_{\alpha} s_{\alpha}^2 / \sum_{\alpha} m_{\alpha})^{1/2} \rangle \quad \text{Eq. 1}$$

where m_{α} is the mass of the α atom, located at a distance s_{α} from the molecule centre of mass, $\langle \rangle$ indicates an average over the N molecules and time.

We have also calculated the number of intramolecular and intermolecular hydrogen bonds (HBs) developed by each tautomer. To do so, we have considered that an HB exists if the oxygen–oxygen distance $d(\text{O-O})$ is smaller than 3.4 Å and the O-H...O angle is larger than 150.0°. This geometric criterion includes only well-formed and strong HBs^{46,47}. It should be noted that use of less stringent criteria ($d(\text{O-O}) < 4.0$ Å, and O-H...O angle $> 120^\circ$) including quite deformed and weaker HBs have given similar results. All those results are given in Supporting Information.

Two amorphous systems respectively composed of only tautomer A and only tautomer C have been investigated from MD simulations. Each simulation box was generated using the same procedure. First, we build an initial cubic pseudo-crystal box composed of 64 molecules. Then, it was melted at a high temperature of 700K during 2ns in the NPT ensemble in order to eliminate any orientational or translational order, and to thus obtain a fully disordered system in the liquid state. Finally, we hyper-quenched the liquid box from 700 K to 300 K at a cooling rate of 10K/100ps. We applied a further equilibration of 8 ns (including 6 ns in the NPT ensemble and 2 ns in the NVT ensemble) to the resulting boxes at 650K, 600K, 550K and 500K. After equilibrations, several MD trajectories of different lengths (see Table 1) were generated at the different temperatures and used to calculate the diffusion coefficients, as well as the gyration radii. The densities of the different boxes are also reported in Table 1.

Table 1: Densities and lengths of the MD trajectories generated at the different temperatures from both systems.

Temperature (K)	Density (± 0.01 g/cm ³)		Simulation time (ns)	
	tautomer A	tautomer C	tautomer A	tautomer C
650	1.29	1.30	20	20
600	1.33	1.35	20	20
550	1.37	1.39	150	150
500	1.41	1.42	150	200

3. Results and discussion

3.1. Structure of processed materials

Figure 2 shows the X-ray diffraction (XRD) patterns of crystalline lactulose recorded at RT after different processing: quenching of the melt (QM), milling (MIL), spray-drying (SD) and freeze-drying (FD). Clearly, the four diffraction patterns are free of Bragg peaks which indicates that each process has produced amorphous lactulose. Moreover, the four patterns appear to be very similar, showing a diffusion halo centred around $2\theta = 18^\circ$. Structural differences between the four amorphous states, if any, are too small to be detected by classical X-ray diffraction. However, it is worth noticing that subtle structural differences between the different amorphous states have been detected by neutron diffraction investigations. These results are reported in details in Ref⁴⁸.

The physical stability of SD, FD, MIL and QM amorphous samples was tested through long annealing at different temperatures. At 20°C, the amorphous samples were found to be stable during 6 months, except the MIL sample which showed slight signs of recrystallisation through the development of tiny Bragg peaks. For higher annealing temperatures, chemical degradation was found to occur before any crystallisation could be observed.

Figure 2: XRD patterns of amorphous lactulose samples: FD (blue line), SD (pink line), MIL (red line) and QM (green line).

3.2. Tautomeric composition of processed materials

Figure 3 shows NMR spectra of crystalline lactulose recorded after the four amorphisation processes: milling (MIL), freeze drying (FD), spray drying (SD), and quenching of the melt (QM). The unprocessed crystal is also reported for comparison. In each case the NMR spectrum was recorded within three minutes after dissolution in DMSO to limit as much as possible any mutarotation due to the dissolution itself. The validity of this protocol is demonstrated in Supporting Information. All spectra show three well defined peaks between 5.2 ppm and 5.7 ppm which are characteristic of tautomers A (5.35 ppm), B (5.66 ppm) and C (5.28 ppm). We can also note strong differences in the relative intensity of the peaks from one sample to another, indicating noticeable differences in the tautomeric composition of the samples. The tautomeric compositions obtained by integration of the peaks are reported in Table 2. It is worth mentioning that the characteristic peaks were assigned on the base of previous studies^{36,39,49}.

In the unprocessed crystal the tautomeric composition appears to be $X_A = 79 \pm 4\%$, $X_C = 10 \pm 4\%$ and $X_B = 11 \pm 4\%$. These values are slightly different from those previously obtained by Jeffrey et al.³⁶ ($X_A = 74\%$, $X_B = 10\%$ and $X_C = 15\%$). However, we have found that the tautomeric compositions can noticeably vary from one batch to another. In particular, X_A and X_C vary respectively in the ranges [74% , 79%] and [10% , 16%] while X_B is almost constant. Variations of X_A and X_C are probably due to the experimental conditions used by the provider to produce the crystalline lactulose.

The tautomeric composition of the QM is different from that of the crystal. In particular, X_A (49%) decreases to the benefit of X_C (34%) and X_B (17%). These changes reveal a strong mutarotation occurring upon melting. Moreover, the QM spectrum shows some additional small peaks which are likely to result from some thermal degradation occurring during melting³⁷.

The tautomeric composition ($X_A = 82\%$, $X_B = 8\%$ and $X_C = 10\%$) of the sample milled during 8h under a dry atmosphere (RH ~0%) appears to be very close to that of the initial crystalline form. This means that the amorphisation induced by milling has occurred without any mutarotation. Such a behaviour was already reported for lactose⁵⁰ and glucose⁵¹. It proves that the amorphisation induced by milling really occurs in the solid state and that the sample temperature never exceeds, even locally, the melting point which would inevitably lead to a strong mutarotation as found for the QM sample. The absence of melting during milling is also proved by the absence of thermal degradation in the NMR spectrum which is characteristic of amorphous lactulose produced by QM. It must also be noted that if the milling is performed under a non-dried atmosphere, a noticeable mutarotation is observed. In that case, the mutarotation is mediated by the free water caught during the milling so that the tautomeric composition converges towards that characteristic of lactulose dissolved into water.

The tautomeric compositions of SD and FD samples are similar to each other, but noticeably different from those of the other compounds. Tautomer C predominates in SD and FD compounds, while tautomer A predominates in the other amorphous samples. These differences of tautomeric compositions are likely to be due to the fact that SD and FD processes require an initial dissolution stage of lactulose. Mayer et al.⁴⁹ have determined the tautomeric composition of lactulose in solution in water at RT. This composition is reported in Table 2 and appears to be very close to that those of SD and FD samples. This suggests that removal of water occurring during SD and FD processes occurs with almost no mutarotation. In the case of freeze-drying the mutarotation is likely to be blocked because the water removal occurs in the solid state where the molecular mobility is almost non-existent. In the case of spray-drying the removal of water molecules occurs on a very short time scale which does not allow mutarotation to occur. As a result, the tautomeric composition of lactulose in solution is preserved in the SD and FD samples.

Figure 3: NMR spectra of different lactulose samples. From top to bottom: crystal (black line), MIL (red line), QM (green line), SD (pink line), QSD (black line), FD (blue line), QFD (black line).

Table 2: Tautomeric compositions and glass transition temperatures of different lactulose samples. The tautomeric composition of lactulose in solution in water⁴⁹ is also reported for comparison.

Samples	tautomer A in % (± 4)	tautomer B in % (± 4)	tautomer C in % (± 4)	T _g (°C) (± 1)
crystal	79	11	10	---
MIL at RH#0	82	8	10	88
In solution [Mayer] ⁴⁹	24	11	65	---
QM	49	17	34	99
SD	29	9	62	98
QSD	50	18	32	88
FD	24	8	68	98
QFD	51	18	31	88

3.3. Glass transition of processed materials

Figure 4 shows the MDSC heating scans (reversible signals) of lactulose amorphised by the different techniques (quenching of the melt, milling, spray-drying and freeze-drying). All of them show a Cp jump characteristic of a glass transition that confirms their amorphous character. Moreover, no sign of exothermic crystallisation could be detected in the total heat flow upon heating (5°C/min) revealing the high physical stability of each amorphous lactulose sample. It must be noted that for the MIL, SD and FD samples the Cp jump occurs in two steps. The first step corresponds to the glass transition itself while the second step is an artefact which is frequently observed in amorphous materials having a complex microstructure⁵². MIL and SD materials are finely divided powders and FD materials are characterised by a high porosity. Both kinds of microstructure have generally a much lower thermal conductivity than bulk amorphous materials obtained by QM giving rise to an apparent lower Cp. Above T_g, the viscosity drops, so that the previous microstructures collapse giving rise to dense droplets of liquid which have a much better thermal conductivity. As a result, the apparent specific heat increases giving rise to the second Cp jump in runs 2, 3 and 4. The glass transition temperatures of the four amorphous lactulose samples, derived from the first Cp jumps, are reported in Table 2. They appear to depend noticeably on the amorphisation technique, ranging from 88°C for the MIL to 99°C for the QM. We show hereafter that this variable T_g is due to chemical changes arising either from thermal degradation or from mutarotation.

Recently, it was reported that the chemical degradation of lactulose on approaching the melting point has a noticeable effect on the glass transition temperature of the quenched melt³⁷. It was shown in particular that the degradation products have an anti-plasticizing effect, increasing the apparent T_g of the amorphous material. Different melting protocol can

thus give rise to slightly different T_g , as it has been observed for several compounds^{35,53}. We have taken advantage of the possibility to obtain non degraded amorphous lactulose by SD and FD to produce quenched liquid lactulose without any thermal degradation. This was done by heating (5°C/min) the SD and FD samples up to 150°C. This temperature is located sufficiently above T_g in order to have the liquid state (although metastable), and sufficiently below the melting point ($T_m = 162^\circ\text{C}$) to avoid any chemical degradation³⁷. The metastable liquids thus obtained have then been quenched to 20°C to form non degraded quenched liquids called QSD (Quenched Spray Dried) and QFD (Quenched Freeze Dried). The NMR spectra of these quenched liquids are reported in figure 3. They do not show the degradations spikes previously detected in the QM sample which proves that QSD and QFD are not chemically degraded. The calculated tautomeric compositions derived from the two spectra are reported in Table 2. It appears that both of them are very close to the tautomeric composition of the QM sample. This means that a strong mutarotation has occurred in the SD and FD samples during their small excursion above T_g , to reach that of the liquid state. The heating DSC scans of the QSD and QFD samples are reported in figure 4 (runs 5 and 6). They both show three interesting features:

- (i) A well-defined glass transition at 88°C occurring through a single C_p jump. Such a single C_p jump indicates that the complex microstructures characteristic of the SD and FD samples have been erased above T_g and replaced by a droplet microstructure typical of quenched melts.
- (ii) The glass transition is noticeably depressed compared to those of SD and FD lactulose. This shift must thus clearly be attributed to the changes in the tautomeric composition previously detected (Table 2).
- (iii) The glass transition of QSD and QFD are also strongly depressed compared to that of the QM, while the three amorphous samples have very close tautomeric compositions. This confirms that the highest glass transition of the QM is due to an anti-plasticization effect arising from degradation products.

The above results indicate that the glass transition temperature of amorphous lactulose depends noticeably on its tautomeric composition. In particular, the analysis of Table 2 shows that the samples rich in pyranose moiety (SD and FD) have a glass transition temperature 10 °C higher than that of samples rich in furanose moiety (QSD and QFD). This suggests that tautomer A has a plasticizing effect on the tautomeric mixture while tautomer C has an anti-plasticizing effect. These behaviours are coherent with those previously detected on fructose by Włodarczyk et al.¹⁶ using Dielectric Spectroscopy. These authors have shown that mutarotation can change the T_g of fructose by 10°C and that the T_g of the pyranose moiety is higher than the furanose one. Moreover, the variation of T_g with changes in the tautomeric composition due to solid state mutarotation is not specific to sugars. It was also noticed in some drugs like glibenclamide⁵⁴ and aberchrome 670⁵⁵, and in some polymers like azopolymers (polymers containing azobenzene) where mutarotation (photo-isomerization) can be interestingly triggered by UV irradiation⁵⁶. All these materials have thus the interesting property to have a tunable T_g which can be varied by some external physical parameters.

In the case of lactulose, a better characterisation of the effect of each tautomer on T_g can hardly be achieved experimentally. The difficulty mainly arises from the impossibility to control the tautomeric composition of amorphous lactulose and to produce amorphous lactulose tautomerically pure. In the next section, we show how numerical simulations can overcome these experimental limitations and give interesting information on the influence of the tautomers (A and C) on the glass transition.

Figure 4: Heating MDSC curves (5 °C/min) of amorphous lactulose samples. From top to bottom: QM (green line), MIL (red line), SD (pink line), FD (blue line), QSD (purple line) and QFD (dark blue line). For reason of clarity, only the reversible signals are represented. The dashed lines mark the position of the glass transition temperature.

3.4. Study of the molecular mobility of tautomers A and C by MD simulations

Molecular mobility of amorphous compounds composed only of tautomer A, and only of tautomer C was studied by MD simulations in order to understand better the differences found concerning the glass transition of the different processed amorphous samples and their link with the tautomeric fractions. The glass transition temperature could be determined by MD simulations from the temperature dependence of the density^{57,58}. Assuming a linear evolution of the density as function of the temperature at very low and very high temperatures, the crossing between the high temperature equilibrium line and the low temperature out of

equilibrium line can usually provide a rough estimation of the glass transition temperature. However, very high cooling rates are used in MD simulations ($\sim 10^{12}$ K/min) compared to experimental cooling rates (~ 10 K/min) which usually lead to an overestimation of T_g of about 100K in some cases and therefore to high discrepancies⁵⁹.

Instead of determining T_g , the molecular mobility of tautomers A and C was studied separately by means of their diffusion coefficient D obtained from the mean-squared displacement (msd) calculated in the liquid state from fully equilibrated MD runs. Since lactulose is a quite viscous liquid on the MD timescales, the diffusive regime can be reached only at relatively high temperatures.

It is worth mentioning that in this work, we have assumed that molecular mobility (as probed by the diffusivity) should have a monotonous behaviour as function of the tautomeric concentration in a mixture. Indeed, since the tautomers A, B and C are similar molecules, they are not expected to develop strong interactions in a mixture, and the T_g of the lactulose tautomeric mixture should obey the Gordon-Taylor law⁶⁰ (with K close to 1) as observed for some other mixtures (lactose/budesonide, lactose/mannitol)⁶¹. Therefore, the determination of molecular mobility of liquids composed of single tautomers should allow to understand T_g differences of mixture observed experimentally.

Figure 5 shows the diffusion coefficients calculated at 500, 550, 600 and 650 K in lactulose boxes having only tautomer A (green line) and only tautomer C (blue line). The obtained values are also reported in Table 3. In the studied temperature range, tautomer A is clearly found more diffusive than tautomer C. Upon decreasing temperature, the difference between the diffusion constant of the tautomers A and C also tends to increase. It suggests that a liquid composed of only tautomers A would possess a lower glass transition temperature than a liquid composed of only tautomers C. It should be noted that this trend is consistent with the results obtained with other time-dependent function such as the coherent intermediate scattering function $S(Q,t)$ of the two tautomers (data not shown here). Therefore, a mixture composed of a higher proportion of tautomer C, as found for the SD lactulose (%A = 29, %C = 62) and the FD lactulose (%A = 24, %C = 68), could be expected to have a higher T_g than a mixture composed of a higher proportion of tautomer A, as found for the MIL lactulose (%A = 82, %C = 10). It is worth mentioning that extrapolation of the diffusion coefficient to $D \approx 10^{-20}$ m²/s using a MYEGA law⁶² shows that the simulated glass transition of the pure tautomer C liquid would be approximately 20K higher than the one of the pure tautomer A liquid. This result is compatible with the experimental T_g obtained on the different compounds. It should also be mentioned that the same calculations have been performed for tautomer B, and the results clearly show that tautomers A and B have the same molecular mobility and diffusivity. Therefore, two main behaviours exist in the different amorphous lactulose compounds: tautomers A and B on the one hand, and tautomer C on the other hand.

The difference in diffusivity between both tautomers A and C can be understood from the difference of the densities reported in Table 1. Indeed, a liquid composed of only tautomers C always seems a bit denser than a liquid composed of only tautomers A. However, this difference is very small about 0.01 or 0.02 g/cm³ and thus of the same order of the uncertainties ± 0.01 g/cm³. Moreover, differences in transport properties of fructose (five-membered ring) and glucose (six-membered ring) have been observed experimentally⁶³, and are well in line with our results. In order to understand better the origin of the molecular mobility difference between tautomers A and C, the distribution of their gyration radii at the different investigated temperatures have been computed. The obtained results at T = 500 K are represented in the inset of Figure 5. As it can be seen, the maximum of the distribution is at slightly higher position for tautomer C compared to tautomer A. In addition, at high gyration radius values, the amplitude of the distributions is higher for the case of tautomer C compared to tautomer A. Same behaviour is also found at 550, 600 and 650 K. All these results indicate that tautomer C would possess a size slightly larger than tautomer A. This difference is particularly well in line with the differences in topology between tautomer C composed of two six-membered rings on the one hand and tautomer A composed of one five-membered and one six-membered ring on the other hand (see Figure 1). Assuming that smaller molecules diffuse faster than larger molecules and vice-versa, this would explain the molecular mobility difference observed between tautomer A and C.

Surprisingly, tautomer C develops less intermolecular hydrogen bonds (HBs) than tautomer A at all temperatures (see Supporting Information) despite its lower diffusivity. Indeed, we could have expected a higher number of HBs for tautomer C. For two other disaccharides, namely trehalose and sucrose, results shown that trehalose molecules develop more intermolecular HBs than sucrose molecules⁴⁷, with a higher glass transition temperature (lower diffusivity) for trehalose: $T_g(\text{trehalose})^{64} = 120^\circ\text{C}$; $T_g(\text{sucrose})^{65} = 69^\circ\text{C}$.

At 500K for example, tautomer A develops about 6.4 ± 0.2 intermolecular HBs while tautomer C develops about 5.8 ± 0.2 intermolecular HBs. Almost no intramolecular (between rings) HBs were developed by each tautomer: about 0.1 ± 0.1 for tautomer A, and 0.3 ± 0.1 for tautomer C were calculated. A thorough analysis of the intermolecular HBs allows us to understand the observed differences. Indeed, the oxygen atom of the CH₂OH groups (three are present in tautomer A and two in tautomer C) develops between 1.2 and 1.6 HBs, with an average value of 1.44 for tautomer A and 1.40 for tautomer C. The oxygen atom of the OH groups not belonging directly to CH₂OH groups (five are present in tautomer A and six in tautomer C) develops between 0.1 and 0.9 HB, with an average value of 0.49 for both tautomers. Clearly, the oxygen atom in the CH₂OH groups always develops more HBs than in the OH groups. This result is expected since the rotation around the C-C bond is allowed, thus increasing the accessibility of the oxygen atom in the CH₂OH group compared to the oxygen atom in the OH group. Therefore, the differences between intermolecular HBs developed by both tautomers are due to the fact that tautomer A has three CH₂OH groups, while tautomer C has only two CH₂OH groups (see Figure 1). It could be noted that tautomer A in the crystalline state³⁶ also form no intramolecular HB. This result gives confidence on the number of HBs calculated by MD simulations.

Our results thus suggest that HBs cannot be used to explain molecular mobility differences in this case. The HBs are not the only intermolecular interactions develop by the tautomers. Additional interactions, such as hydrophobic C-C ones, might also impact the molecular mobility of the tautomers. The overall intermolecular interaction energy of both tautomers should be calculated to check this assumption.

Table 3: Diffusion coefficients of tautomers A and C at different temperatures. The uncertainties on those values are very small and have not been reported.

Temperature (K)	Diffusion coefficients ($\times 10^{-9} \text{ m}^2/\text{s}$)	
	Tautomer A	Tautomer C
650	19.581	13.731
600	5.3082	3.7256
550	1.2750	0.4711
500	0.073108	0.015084

Figure 5: Diffusion coefficients of tautomers A (green points) and C (blue points) as a function of the temperature. The data are fitted with a MYEGA law⁶². Diffusion coefficients of tautomer B (not shown) are very similar to tautomer A. The inset shows the distribution of

the gyration radii of tautomers A (green line) and C (blue line) calculated at 500K. Same behaviour is also found at 550, 600 and 650 K.

4. Conclusion

In this paper, we have investigated the influence of the amorphisation route on the physical and chemical properties of amorphous lactulose. Four amorphisation routes have been explored: quenching of the melt, high energy milling, freeze drying and spray drying. Special attention has been paid to the tautomeric composition and to its influence on the glass transition temperature. It appears that the tautomeric composition of each amorphous state reflects that of the physical state preceding the amorphisation process. In particular, the tautomeric composition is that of the liquid state for the quenched liquid, that of the crystal for the milling induced amorphous sample and that of lactulose in solution for the spray-dried and freeze-dried samples. The different tautomeric compositions have been found to have a noticeable repercussion on the glass transition which can vary in the range [88°C; 99°C]. The results also indicate that tautomer A has a plasticizing effect on the tautomer mixture while tautomer C has an anti-plasticizing effect. Molecular dynamic simulations have confirmed this point and have shown that the molecular size could be responsible of this difference of mobility between the tautomers.

Acknowledgment

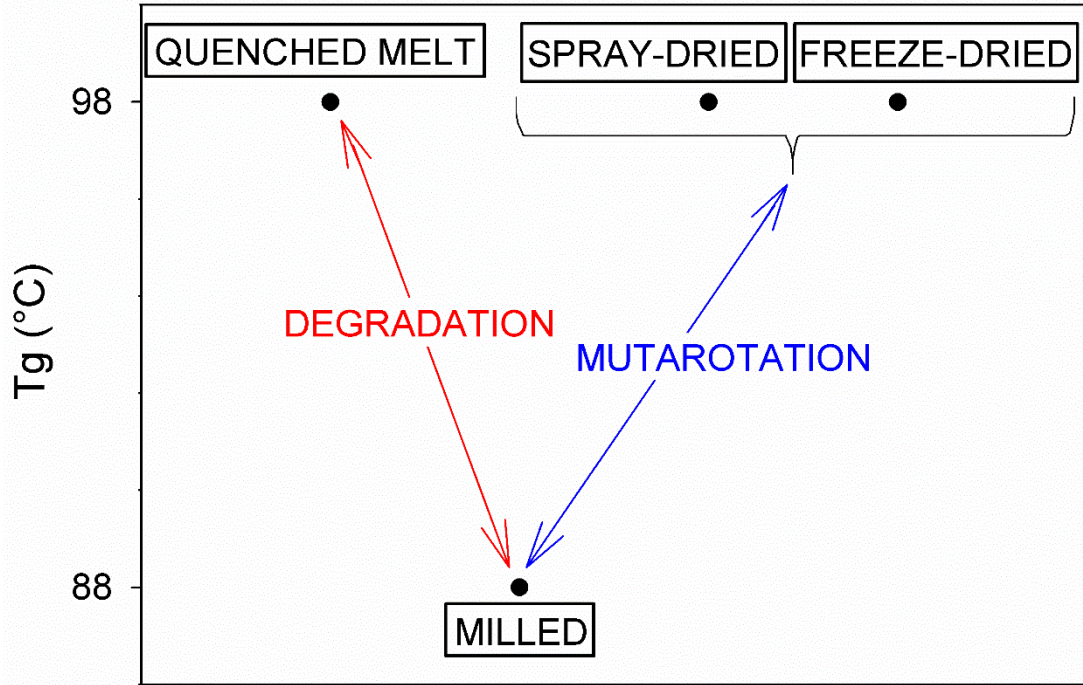

This project has received funding from the Interreg 2 Seas programme 2014-2020 co-funded by the European Regional Development Fund under subsidy contract 2S01-059_IMODE.

F. NGONO thanks the ILL PhD program and the University of Lille for their financial support.

We thank very much Dr. Adrien Lerbret for all the fruitful discussions.

Supporting Information Available: Two sections are presented. The first one shows ability of DMSO to slow down mutarotation in lactulose. The second one shows the number of intermolecular and intramolecular HBs developed by tautomers A and C at different temperatures, using four different geometric criteria to determine the HBs: $d(\text{O}\dots\text{O}) < 3.4 \text{ \AA}$ and $(\text{O-H}\dots\text{O}) > 120^\circ$; $d(\text{O}\dots\text{O}) < 3.4 \text{ \AA}$ and $(\text{O-H}\dots\text{O}) > 150^\circ$; $d(\text{O}\dots\text{O}) < 4.0 \text{ \AA}$ and $(\text{O-H}\dots\text{O}) > 120^\circ$; $d(\text{O}\dots\text{O}) < 4.0 \text{ \AA}$ and $(\text{O-H}\dots\text{O}) > 150^\circ$.
