## Abstract

Parkinson's disease (PD) is a neurodegenerative disorder characterized by loss of dopaminergic neurons in the substantia nigra, and accumulation of iron and alpha-synuclein; it follows a characteristic pattern throughout the nervous system. Despite, decades of successful preclinical neuroprotective studies, no drug has then shown efficacy in clinical trials. Considering this dilemma, we have reviewed and organized solutions of varying importance that can be exclusive or additive and outline approaches to help generate successful development of neuroprotective drugs for PD: 1) select patients in which the targeted mechanism is involved in the pathological process associated with the monitoring of target engagement; 2) combine treatments that target multiple pathways; 3) establish earliest interventions and develop better prodromal biomarkers; 4) adopt rigorous methodology and specific disease-relevant designs for disease-modifying clinical trials; 5) customize drug with better brain biodistribution; 6) prioritize repurposed drugs as a first line approach; 7) adapt preclinical models to the targeted mechanisms with translational biomarkers to increase their predictive value.

## Introduction

Parkinson's disease (PD) is a complex neuropsychiatric disorder.<sup>1,2</sup> It is a progressive and topographically extensive neurodegenerative disease, with a classical pathological hallmark that involves dopaminergic neuron regulated cell death, notably in the substantia nigra pars compacta (SNpc). It is associated with iron accumulation, oxidative stress, nitrosative stress, lipid peroxidation, neuro-inflammation, glutamate excitotoxicity, mitochondrial deficits, lysosome and proteasome alteration with protein misfolding notably of alpha synuclein ( $\alpha$ -syn) with aggregates.<sup>3-5</sup>

Many preclinical studies have identified efficient therapeutic strategies that work well in animal models of PD, but so far, none of them has been confirmed to be effective in clinical trials in patients (**Figure 1**). Consequently, many pharmaceutical and biotechnology companies have been reluctant to enter or even remain in the field of PD drug development. One conceivable fundamental problem for the repetitive failure to convert positive pre-clinical results into therapeutic success might be that PD does not consist of a single disorder, but rather, it consists of a syndrome that shares only weak biologic commonalities and thus requires a careful molecular and clinical triage.<sup>6</sup>

Another major difficulty in developing clinical trials for neuroprotection is the fact that the brain is not accessible for *in vivo* neuronal counts, and therefore there are no tools in the clinic capable of monitoring neuroprotection. Consequently, the term "disease modifier" was introduced in the field (**Figure 2**). The concept of a disease modifying agent implies that it is able to demonstrate a tangible impact on molecular mechanisms known to be involved in the degenerative process. Currently, many of these cannot be fully demonstrated in patients due to limitations in brain accessibility, and the lack of suitable biochemical imaging markers. In this review, we identify and discuss seven current limiting factors of neuroprotective strategies and propose solutions for each of these to help develop efficient treatments aiming at reducing the rate of downward trajectory of disease progression in PD (**Figure 3**). Importantly, these solutions are not of equal importance, some of them being exclusive and others additive.

## Search strategy and selection criteria

To the best of our knowledge, there is no review describing the strategies required for a translational development of a treatment for neuroprotection in PD. References for this review

1  
2  
3 were identified by searches of PubMed between 1969 and July 2020. The search terms were  
4 guided by two strategies: 1) recent reviews on each topic and 2) examples to illustrate the  
5 concepts and the solutions.

### 10 **Challenge 1: PD is not just “heterogeneous” or “complex” but a syndrome.**

11 PD belongs to the wide range of complex multifactorial and polygenic disorders influenced  
12 both by genetic and environmental factors, and is very likely a combination of both in a large  
13 proportion of PD patients. Less than 10% of PD cases have a monogenic origin. The known  
14 causal mutations affect 15 genes and explain only about 30% of monogenic (and 3–5% of  
15 sporadic) cases.<sup>6</sup> Moreover, the monogenic forms display a variable penetrance, variable  
16 expression and a very long pre-symptomatic phase, suggesting that other causal and risk factors  
17 are involved in the pathogenesis. Unbiased genome-wide association studies (GWAS) have  
18 demonstrated a role of more common genetic variants, leading to the concept of ‘graded risk’,  
19 which is a continuum from Mendelian mutations, low frequency disease-causing mutations,  
20 and common polymorphisms with an associated strong-to-low impact on the disease expression  
21 and progression.<sup>7-11</sup> A similar level of complexity of provenance applies to our understanding  
22 of the environmental toxic causes of PD.<sup>12</sup> Exposure to pesticides have been reported to increase  
23 the risk of developing PD, especially for farmers employing organo-chloride chemicals,<sup>13-15</sup>  
24 exposure to MPTP<sup>16</sup>, and intoxication by n-hexane,<sup>17</sup> atypical French Caribbean  
25 Parkinsonism.<sup>18</sup> Noteworthy, most of these environmental compounds are inhibitors of  
26 mitochondrial complex 1, which suggests this as a specific pathway of neurodegeneration. This  
27 complicated situation might be made even more complex due to the behavioral consumption of  
28 substances during one’s lifetime that might themselves also alter PD progression. Indeed, the  
29 risk of developing PD has been shown to be lower in smokers than in non-smokers,<sup>19,20</sup> or in  
30 individuals treated by anti-inflammatory drugs such as Ibuprofen.<sup>21</sup> Consequently, it is  
31 important to consider the various etiologies and risk factors of PD on one hand whilst, on the  
32 other hand, also actively consider the positive and negative risk factors that influence the rate  
33 of disease progression. A major limitation of most neuroprotective PD clinical trials is that the  
34 precise etiology of the disease, and the prior individual environmental exposures of the patients  
35 recruited into these studies, remains unknown.

55

### 56 **Solution 1: To develop clinical trials on patients with known etiology and risk factors**

57 In a diabetic patient, no one would prescribe anti-diabetic drugs without considering the  
58 patient’s dependency on taking insulin. However, it is exactly this type of mistake we are  
59  
60

1  
2  
3 making in the field of PD by including patients with mixed etiologies in neuroprotection trials.  
4 There is now a clear need for changing the strategy and performing clinical trials on well-  
5 characterized populations of patients. Despite the small number of patients with a genetic origin  
6 of their disease, clinical trials should be developed on populations of patients with identical  
7 mutations. Furthermore, the diagnosis of PD should be validated by combining specific clinical  
8 criteria (MDS)<sup>22,23</sup> and imaging of dopamine depletion for inclusion criteria of de novo  
9 patients.<sup>24,25</sup> This is especially important in carriers of PD causative mutations, as they might  
10 still be in a presymptomatic stage of the disease. Furthermore, because in patients with identical  
11 mutations the clinical and pathological expression of the disease might vary,<sup>7,9</sup> selecting more  
12 homogenous subpopulations according to the rate of progression of the disease and prognosis  
13 factors should be the gold standard. Indeed, in de novo patients, probable predictors of more  
14 rapid motor decline and disability could be used - such as higher age at onset, baseline motor  
15 impairment with higher postural instability, and gait disorders score (non-tremor dominant  
16 subtype), cognitive impairment and depression.<sup>26,27</sup> However, specific criteria validated with a  
17 rigorous approach on large cohorts are still lacking.<sup>28</sup>

27  
28  
29  
30  
31 Even patients with exactly the same mutation can display different phenotypes. This is very  
32 likely due to different environmental exposures during life, as well as incomplete penetrance.  
33 Thus, the concept of 'graded risk' developed from genetic research needs to associate the  
34 environment causes and risk factors. The genetic approaches that identify very rare causative  
35 mutations underlying monogenic forms and common variants with small effects need to be  
36 associated with questionnaires and biological samples for environmental factors,<sup>12-19</sup> the co-  
37 morbidities, and the antiparkinsonian and other treatments. By comparing large cohorts of  
38 patients and controls, machine learning and deep learning might allow stratifying the various  
39 subpopulations according to the risk factors of developing PD with omics and epigenetic  
40 analyses to develop the future biomarkers of patient stratification for upcoming trials.<sup>8</sup> The  
41 same strategy needs to be developed on longitudinal cohorts of patients with respect to the  
42 accurate selection of trial end points of disease progression, or time to chosen milestones, or  
43 the novel weighted composite endpoint (PDCORE)<sup>29</sup>.

44  
45  
46  
47  
48  
49  
50  
51  
52  
53  
54 Altogether, a better characterization of the patients in terms of the causes and the factors of their  
55 disease progression will lead to a better stratification and to reduce patient variability in order  
56 to improve the statistical accuracy of the outcomes and end-points measured (**Figure 3**).

57  
58  
59 **Challenge 2: Targeting single pharmacological pathways is not efficient**

1  
2  
3 The mechanisms leading to neurodegeneration in PD include multiple pathways.<sup>3-5</sup> Ultimately,  
4 neurons die by regulated cell death. However, 14 separate types of cell death have now been  
5 defined.<sup>55</sup> Apoptosis, ferroptosis, necroptosis, autophagy and parthanatosi (target of rapamycin  
6 (mTOR) poly (ADP-ribose) (PAR) polymerase-1 (PARP-1)) appear to be particularly relevant  
7 for PD.<sup>56-59</sup> Yet, further studies are required to better characterize the exact types of cell death  
8 that are most relevant in PD neurodegeneration. Importantly, recent research in cancer has  
9 demonstrated that, while there are distinct individual forms of cell death involved, they also  
10 display key connections between them, notably between ferroptosis, autophagy and  
11 parthanatosi.<sup>60,61</sup> In addition, whether these molecular and cellular interactions represent a  
12 cause or a consequence of neurodegeneration in PD still needs clarification. An important issue  
13 for developing efficient neuroprotective trials is to determine whether the molecular changes  
14 involved actually belong to the same molecular pathways or instead to parallel pathways (i.e.  
15 different pathways). Of course, a broad action on several pathways will largely increase the  
16 chance of success.

### 27 28 29 **Solution 2: Identify all PD-relevant pathways of cell death and combine treatments that** 30 **target multiple pathways**

31  
32 Identifying the interactions between the molecular and cellular changes seen in PD is a key  
33 requirement in terms of informing how best to establish robust neuroprotection. Of course, if  
34 they belong to the same pathway blocking the deleterious mechanism, whether upstream or  
35 downstream to these molecular targets, this will result in the same protective effect and a single  
36 drug might therefore likely be highly efficient. On the other hand, if they belong to parallel  
37 pathways, then blocking one of these will not result in neuroprotection since the deleterious  
38 effects of the other pathway will still contribute to the neurodegenerative process. It has been  
39 exemplified in experimental models of PD that mitochondrial complex 1 deficiency and  
40 proteasome dysfunction belong to parallel pathways.<sup>62</sup> Thus, if this is similarly true in human  
41 pathology, then disease-modifying clinical trials will require a combination of two or more  
42 drugs, and thereby targeting multiple pathways involved in neurodegeneration. Alternately, one  
43 might consider using drugs with a pleiotropic action, or using an appropriate combination of  
44 drugs. Yet, drug agencies still require proof of efficacy of each single drug – as monotherapies  
45 - before approving the development of any combinations of these drugs. But such a multi-drug  
46 strategy has already been proven to be highly successful in the fields of cancer, HIV and  
47 tuberculosis. Future neuroprotective strategies in PD should similarly test combinations of  
48 drugs selected on the basis of the various relevant mechanisms of cell death in any given  
49

2  
3 subtype of PD. This strategy has recently started in amyotrophic lateral sclerosis with a  
4 combination of two drugs already in use (sodium phenylbutyrate and tauroursodeoxycholic  
5 acid).<sup>63</sup> However, this strategy will not overcome the problem of whether any of the pathways  
6 targeted are truly at play in the population recruited for those trials.  
7  
8  
9

### 11 **Challenge 3: Neuroprotective interventions are initiated too late in the course of the** 12 **disease**

13  
14  
15 Most clinical trials are started a few years after the onset of symptoms, partly to ensure all  
16 enrolled patients have a reliable diagnosis of PD. Yet, imaging studies of dopaminergic markers  
17 have estimated there is a preclinical period of 15 to 20 years in younger, and 10 years in older,  
18 PD patients.<sup>30</sup> By the time motor symptoms appear, patients have, lost 80 percent of their striatal  
19 dopamine, corresponding to 50% loss of dopaminergic neurons in the substantia nigra.<sup>31,32</sup>  
20 Additionally, neuropathological examinations have, years before the SNpc is affected, shown  
21 lesions in the olfactory bulb, mesenteric plexus, brainstem including locus coeruleus, and raphe  
22 nucleus.<sup>16,33</sup> Finally, the neurodegenerative process might by itself engage a self-perpetuating  
23 phenomenon as shown in the human subjects intoxicated by MPTP. Thus, it is clear that late  
24 therapeutic intervention obviously decreases the chance of success.  
25  
26  
27  
28  
29  
30  
31  
32  
33

### 34 **Solution 3: To establish early interventions and develop better prodromal biomarkers**

35  
36 The prodromal phase is theoretically the best period to start any neuroprotective treatment, and  
37 it should ideally be initiated before any important damage of the nigro-striatal pathway has  
38 occurred corresponding to the first stages (1 and 2) of Braak's classification.<sup>33</sup> However, there  
39 are two major limitations. i) The spectrum of symptoms during these early Braak's stages  
40 remains complex and very variable among patients.<sup>34,35</sup> ii) Some individuals recruited during  
41 the prodromal phase may not express the disease, or may only develop it very late. This calls  
42 for a search of better diagnosis biomarkers (wet, dry, wearable) during the prodromal phase of  
43 the disease, and incorporating likelihood ratios with age and gender (of developing overt PD),  
44 and improved predictive algorithms generated by big data approaches to predict the likelihood  
45 of progression into the symptomatic phase.<sup>35-38</sup>  
46  
47  
48  
49  
50  
51  
52  
53

54  
55 Until now de novo patients have constituted the best population for neuroprotective trials, with  
56 the aim that the remaining dopaminergic neurons can be saved.<sup>39-42</sup> Furthermore, at this stage,  
57 there is no interference of dopaminergic treatment on the analysis of any neuroprotective effect.  
58 However, it is difficult to recruit de novo patients for several reasons. 1) There is a risk of  
59  
60

1  
2  
3 including atypical forms and lack of dopamine depletion. 2) There is a higher patient dropout  
4 rate because patients are stressed, or in denial, after receiving their diagnosis, and may poorly  
5 tolerate the lack of symptomatic treatment.<sup>42-45</sup> Another alternative is to perform the trials on  
6 early PD patients (within the first 3 years after diagnosis) because they receive a stable,  
7 moderate-dose regimen of dopaminergic drugs and could still benefit from an intervention that  
8 would reduce the rate of disease progression. Furthermore, these patients are easy to recruit and  
9 allow studying the interactions between the neuroprotective compound and dopamine agonists  
10 and/or L-dopa.<sup>42-45</sup>

11  
12  
13  
14  
15  
16  
17  
18  
19 The ideal population of patients to include in neuroprotective trials are those characterized by  
20 a genetic trait, or by a biomarker that would confirm the diagnosis during the presymptomatic  
21 phase and that can demonstrate the molecular susceptibility to the mechanism of the drug to  
22 which it is exposed. Asymptomatic carriers of mutations causative of PD represent the best  
23 population to study. Yet, in such patients, the onset of the symptoms is very difficult to predict.  
24 One strategy would consist of performing neuroprotective trials in these patients a few years  
25 before the mean age of onset in such a specific population. The read-out of these types of  
26 neuroprotective studies would then be the “delayed time to transition” to the symptomatic  
27 phase. Yet, such patients are relatively rare and inclusion difficulties might prevent extensive  
28 clinical trials unless run as a global effort. Furthermore, because of the variability in the duration  
29 of the asymptomatic phase due to variable penetrance of the genes involved, such initiatives  
30 might also require long study durations, thereby increasing their cost.<sup>6,42-45</sup>

31  
32  
33  
34  
35  
36  
37  
38  
39  
40  
41 Because of the difficulties in performing clinical trials in inherited forms of PD, neuroprotective  
42 approaches should also be tested in sporadic cases. To do this, there is a need for diagnostic  
43 biomarkers during the prodromal phase of the disease. Many studies have attempted to identify  
44 such wet and dry biomarkers.<sup>6,38,40,42,43,45-48</sup> Among those candidates,  $\alpha$ -synuclein ( $\alpha$ -syn) is  
45 regarded by many as the most promising.<sup>6,33,41</sup> However, PD is usually associated with  
46 abnormal accumulation of several other types of misfolded proteins, notably  $\beta$ -amyloid and tau,  
47 which co-occur with  $\alpha$ -syn.<sup>6,33,41</sup> Moreover, Lewy pathology is not necessarily found in all  
48 forms of PD (e.g. some leucine-rich repeat kinase 2 (LRRK2) patients, and most of the Parkin-  
49 related cases).<sup>6,48</sup> Furthermore, even in cases with clear synucleinopathies, there is no dose-  
50 dependent correlation between Lewy pathology, cell loss and clinical features.<sup>49,50</sup>  
51 Consequently,  $\alpha$ -syn represents a convenient pathologic biomarker but may not be pathogenic  
52 with the exception of  $\alpha$ -syn-related genetic PD patient subtypes.<sup>51-54</sup> Moreover,  $\alpha$ -syn

determination in fluids or peripheral tissues cannot be the sole surrogate biomarker of PD because its concentration is modified by complex physiopathological responses within the body, as well as being modified by the consequences of PD neurodegeneration. Further studies are required to analyze the dynamic expression and deposition of  $\alpha$ -syn during PD disease progression, ideally using a translational approach.

#### **Challenge 4: The methodology of clinical trials is not adapted to progressive long-term neurodegeneration**

The design of disease-modifying, neuroprotective clinical trials in PD patients is very challenging for several reasons. First, there is no reference drug, nor any clinical trial design, that has ever shown efficiency for neuroprotection. This might be due to the lack of efficacy of the tested drugs and/or from poor clinical trial designs, or both. This problem is even more complex in PD because the tested medications might have both a symptomatic and a neuroprotective effect. Second, biomarkers of neuroprotection are still lacking and it is therefore difficult to determine on rational scientific grounds whether or not the drug being tested is actually reaching its biological target and is thereby having a positive effect at a cellular level. Thus, clinical trials mostly rely on clinical outcomes. However, the clinical symptoms are, themselves, not very sensitive to be able to demonstrate meaningful change since they do not progress rapidly enough to measure accurately, at least not over the study durations, typically 1 year, chosen for most neuroprotective clinical trials in PD patients. Third, even with well-validated scales such as UPDRS, drug testing of putative neuroprotective agents is not typically performed in a real-life environment. Finally, the global handicap (i.e. motor, cognitive and behavior), also including the rather more variable non-motor symptoms, needs to be considered. All of this, calls for new designs of neuroprotection trials in PD.

#### **Solution 4: To adopt rigorous methodology and specific disease-relevant designs for PD neuroprotective clinical trials**

It is clear that greater attention must be paid in selecting the most appropriate clinical trial design, with either an adaptation of a well-tested design, or new approach depending on any suspected possibility or likelihood that the neuroprotective drug under investigation may also have a concomitant symptomatic effect.<sup>6,42-45</sup> (Figure 3) Adaptive trials have been also proposed as a version of the responder trial.<sup>71</sup> A first discovery phase includes a broad population with several subtypes followed by a validation phase considering only the best patient responders. Master protocols, including “basket trials”, “umbrella trials”, and “platform

1  
2  
3 trials”, use a trial network with shared infrastructure and are designed with multiple sub-studies  
4 to evaluate one or more investigational drugs in one or more disease subtypes.<sup>72,73</sup> Following  
5 the same idea, multi-arm, multi-stage (MAMS) trials have been recently proposed to test many  
6 potential therapies currently in the pipeline in parallel (multi-arm), transitioning seamlessly  
7 through various phases (multi-stage), i.e., from a phase II safety and efficacy study to a phase  
8 III trial, with the help of a platform.<sup>74</sup> While they are attractive, they come from the oncology  
9 field where the simultaneous therapeutic use of multiple drugs is already validated and accepted  
10 by regulatory authorities, which is far from the current case for PD.

11  
12 The demonstration of the reduction of an already slow disease progression is very challenging  
13 since it requires a long-term study during which the symptomatic dopaminergic requirements  
14 of patients are frequently changing, and this can greatly confuse the interpretation of  
15 neuroprotective results. Regarding the duration of the trial, if a symptomatic treatment is not  
16 introduced or modified, a period between 6 to 12 months represents a reasonable and practical  
17 compromise between having sufficient time to observe a neuroprotective effect and the  
18 relatively limited number of patient dropouts set against an attrition of study subjects that  
19 inevitably continues to increase over longer trial durations. For example, a study duration of 6  
20 months in de novo patients was associated with a drop-out rate of 10-15% in the ADAGIO  
21 trial.<sup>75</sup> Conversely, a 9-month period would have a greater chance of clinical success but at the  
22 expense of a higher drop-out rate in de novo patients.<sup>45</sup>

23  
24 The current MDS-UPDRS clinical scales are not designed to assess subtle modifications of  
25 disease progression. This low sensitivity to monitor change requires a very large population of  
26 patients to be followed for long periods of time, and this is very challenging for Phase II trial  
27 purposes. Using a biomarker as a primary outcome measure is an interesting alternative for an  
28 early phase II study. Objective and continuous measures offer a different perspective, with  
29 wearable technologies provide specific and rigorous quantification that could become efficient  
30 biomarkers of motor handicap in real life spanning over several days, such as, connected  
31 actimetry<sup>76</sup> and connected soles for a continuous recording of gait and balance.

### 32 33 **Challenge 5: Targeting the central nervous system (CNS) represents a pharmacological** 34 **challenge**

35  
36 Another major challenge relates to the poor blood-brain-barrier (BBB) penetration of many  
37 candidate neuroprotective drugs. The competitive and variable drug penetration in the brain  
38 parenchyma leads to low and unpredictable bio-distribution in the CNS with additional  
39  
40  
41  
42  
43  
44  
45

56  
57  
58  
59  
60

1  
2  
3 confounding interference from dietary foods and drug interactions etc. Furthermore, for most  
4 of the drugs there is no measurement of its concentration in the brain parenchyma, nor of its  
5 engagement with its biological target in neurons. Thus, clinicians currently only rely on clinical  
6 scales or, in the best cases, also on various available imaging parameters of the brain.  
7  
8  
9

10  
11 The issue of BBB drug penetration might also be challenging due to blood vessel modifications  
12 associated with the disease process or the medication<sup>77,78</sup>  
13  
14  
15

### 16 17 **Solution 5: To customize drug with better and more selective brain accessibility**

18 Pharmacokinetic studies with drug concentration measurements should be associated in both  
19 preclinical and clinical studies. Yet, this is complex because cerebrospinal fluid (CSF) is not  
20 accessible on a repetitive basis and only gives a biased measurement of the drug concentration  
21 in the brain region targeted by the drug. Furthermore, sampling of both CSF and blood as a  
22 function of time after administration provides an estimate the precision of which will depend  
23 on the number of samples over time. The association of brain tissue and clinical measures -  
24 respectively in both the experimental models and the patients - should ideally allow the  
25 establishment of an algorithm to help select the best dose and regimen in humans.  
26  
27  
28  
29  
30  
31  
32  
33

34 Another need is to improve drug penetration into the brain by customizing drugs with better  
35 penetration characteristics, or by developing prodrugs that will easily cross the BBB. Indeed,  
36 oral administration is obviously the easiest, but not the best, method of drug delivery for brain  
37 diseases. Transnasal delivery is also noninvasive and easy to operate and should be considered  
38 for intermittent administration of small molecules or small volumes of drug.<sup>79</sup> Only small and  
39 lipophilic drugs can readily penetrate into the brain. In the situation where a very effective  
40 neuroprotective drug poorly penetrates the BBB, then several options might be usefully  
41 considered to help improve its brain penetration. The first option for small molecules is to  
42 increase their lipidation, or to reduce their size, keeping only the active neuroprotective  
43 fragment. Another interesting option is to use a lipophilic prodrug.<sup>80,81</sup> Nanoparticles represent  
44 another chemical modification to increase BBB permeability (**Figure 3**).<sup>82,83</sup>  
45  
46  
47  
48  
49  
50  
51  
52

53 If, despite chemical modification, the drug does not penetrate into the brain parenchyma then  
54 instead, direct delivery in the brain might be considered.<sup>84</sup> The procedure involving intrathecal  
55 administration of baclofen or painkillers has been reported to be effective, reversible, and safe  
56 in thousands of patients.<sup>85</sup> The safety of brain infusion of growth factors has also generated  
57 promising results despite a lack of efficacy for neuroprotection.<sup>86</sup> With such procedures, high  
58  
59  
60

1  
2  
3 local drug and personalized concentrations can be achieved with no or minimal systemic  
4 adverse events.  
5  
6  
7

8 Developments using physical, chemical and biological methods to open the BBB have also  
9 emerged recently. For example, focused ultrasound (FUS) has been shown to be safe and very  
10 efficient. Such approaches represent an interesting alternative for intermittent administration of  
11 drugs with long lasting effects.<sup>87,88</sup> Co-administration of or substances acting on the efflux  
12 carriers, and transporters, can also theoretically increase drug penetration.<sup>84</sup>  
13  
14  
15  
16  
17  
18

### 19 **Challenge 6: Neuroprotection represents a very long and risky drug development**

20 Developing a new drug is always very long (an average of 14.2 years), very expensive (US  
21 \$802 million) and challenging.<sup>89</sup>  
22  
23  
24  
25

### 26 **Solution 6: To reduce the risk of drug development for PD**

27 Additional safeguards need to be developed with combined efforts both from academic partners  
28 and the drug industry. Prioritizing the development of repurposed drugs represents an attractive  
29 approach for neuroprotection in PD. Drugs already on the market for other therapeutic  
30 indications have the advantage of being already used for humans, and helpfully already have a  
31 well-known safety profile. Because of the extensive experience with these compounds they are  
32 generally also straightforward to test in preclinical models. Generally, their pharmacokinetic  
33 and pharmacodynamic characteristics are known, but the issues of brain penetration and  
34 adaptation of the dosage to the CNS might not be trivial. In terms of intellectual property, a new  
35 patent of an old drug for a new indication or formulae typically allows increasing the time for  
36 development for use in another indication. Target validation and lead molecule optimization  
37 can then be developed based upon this safe, first-in-class, repurposed drug.  
38  
39  
40  
41  
42  
43  
44  
45

46 Another way of reducing the risk for drug development in neuroprotection is based on the fact  
47 that a few drugs may have shown efficacy in animals, and then also shown encouraging  
48 results in humans, but were subsequently abandoned because of their toxicity in a very small  
49 number of patients. Yet, even if a drug does not have an ideal safety profile, rigorous  
50 monitoring can allow testing it in clinical trials. Deferiprone is currently being clinically  
51 assessed for conservative iron chelation despite a rare risk of agranulocytosis (<0.8%).<sup>90,91</sup>  
52  
53  
54  
55  
56  
57

### 58 **Challenge 7: Animal models of PD are not predictive of clinical efficacy**

1  
2  
3 No molecule that has demonstrated positive *in vitro*, and *in vivo*, effects on neuroprotection  
4 has displayed any neuroprotective effect in clinical trials.<sup>42,64</sup>  
5  
6  
7

8 **Solution 7: To adapt preclinical models of PD and research design to the clinical**  
9 **situation**

10 One of the reasons for the lack of predictive value of any of the PD animal models is the fact  
11 that these models cannot recapitulate the clinical situation. Animal models can inform about  
12 mechanisms of therapy but not about patient selection for that therapy. This is why one should  
13 associate, in a translational manner, dry and wet biomarkers of the targeted mechanisms both  
14 in the models, and in humans, to ascertain neuroprotection.  
15  
16  
17  
18  
19

20  
21  
22 The prediction of neuroprotection requires human, non-oncogenic, cell models including  
23 LUHMES, primary dopaminergic neuron culture, patient-derived Inducible Pluripotent Stem  
24 cells and three-dimensional brain organoids<sup>65</sup>.  
25  
26  
27

28  
29 Several *in vivo* models have been generated through neurotoxin-based or genetic-based  
30 approaches in rodents, or non-human primates, to demonstrate and validate neuroprotection.  
31 Neurotoxin-induced models reproduce some of the key molecular alterations such as complex  
32 1 deficiency, or proteasomal dysfunction. Chemicals such as 6-hydroxydopamine, MPTP,  
33 rotenone, annonacine, and paraquat are mainly used to generate these types of PD models.  
34 Protein accumulation can be generated via overexpression of  $\alpha$ -syn. In addition, protein  
35 aggregation pathology can be triggered by inoculating preformed fibrils of  $\alpha$ -syn in the brain.<sup>66</sup>  
36 Yet, a limitation of these models is that not all of the molecular changes seen in PD actually  
37 coexist in a single model. It may be useful, to increase the prediction by associating different  
38 experimentations in different *in vivo* models (toxin and genetic hits), to reproduce far better the  
39 full pathological process as typically seen in PD.<sup>66</sup>  
40  
41  
42  
43  
44  
45  
46  
47  
48

49 Another important issue of neuroprotection trials is that, even for a same mutation, the clinical  
50 phenotypes of the patients recruited into a trial do vary considerably. Preclinical  
51 neuroprotection studies should therefore be performed using animals of mixed genetic  
52 backgrounds, and not on inbred animals from an identical genetic provenance, but this may  
53 necessitate an increase in the required number of animals to achieve statistical significance.  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 The immune status of animals is also important to monitor because neuroinflammatory  
4 processes also participate to neuronal degeneration. Indeed, most preclinical studies are  
5 performed on animals housed in a sterile environment, but PD patients in their daily lives are  
6 in constant contact with multiple immune stimulating agents. Lipopolysaccharide, a bacterial  
7 membrane molecule well known for its immune stimulating properties, increases the sensibility  
8 to parkinsonian toxins in rodents.<sup>67</sup> Such a phenomenon might even start very early during life  
9 as offspring of pregnant rats injected with LPS are also more sensitive to parkinsonian toxins.<sup>67</sup>  
10 One should thus consider monitoring carefully the immune status of the animals or perhaps  
11 even house the animals in standard non-SFP facilities.  
12  
13  
14  
15  
16  
17  
18  
19

20 Because PD is in most cases associated with aging, preclinical studies should include old  
21 animals. Indeed, elderly humans, and old animals, show less neuronal plasticity<sup>68</sup> a lower level  
22 of dopamine metabolism<sup>69</sup> and a higher iron content (which increases the pro-oxidant status<sup>70</sup>),  
23 and they also display considerably different dose-related effects to drugs given. PD is more  
24 prevalent in men, but both genders need to be accurately assessed because huge differences  
25 between them can be observed in terms of dose effects and neuronal degeneration.  
26  
27  
28  
29  
30  
31

32 The chronicity (months or even years) both of the degenerative process, and of the treatment  
33 regimen given, as well as the time at which the treatment is first introduced (ideally at time of  
34 the onset of symptoms) should be accurately reproduced in animal models.  
35  
36  
37  
38

39 Finally, good practice standards should be used in preclinical studies just as is the case in the  
40 clinical studies (**Figure 3**). Such standards are costly and will dramatically reduce the number  
41 of studies but will undoubtedly increase their predictability.  
42  
43  
44  
45

## 46 **Conclusion**

47 We have described a number of critical hurdles that are currently hampering progress towards  
48 bringing effective neuroprotective therapeutic approaches to slow disease progression in  
49 patients with Parkinson's disease, which arguably represents the greatest unmet need in this  
50 therapeutic area. We do not believe any of these hurdles are intractable and, especially  
51 considering the wealth of promising new neuroprotective approaches that are currently  
52 emerging, we have therefore outlined and organized exclusive or additive solutions of varying  
53 importance to help generate successful development of neuroprotective drugs for PD solutions  
54 and approaches to help overcome most or all of these hurdles.

## Legends

### **Figure 1: Past and current therapeutic strategies illustrating the need of biomarkers of target engagements**

Main physiopathological mechanisms (orange boxes) with complex and multiple interplays (arrows to show that they are in fact all connected), failed past therapeutic strategies (light blue boxes), strategies currently in clinical trials (dark blue boxes). (sources:<sup>42,92</sup> and [www.clinicaltrials.gov](http://www.clinicaltrials.gov)). None of the past and failed trials matched the therapies tested with the suitable molecular biology of the intended recipients. Thus, there is an urgent need of biomarkers that can demonstrate the molecular susceptibility to the mechanism of the drugs in order to validate target engagement and to assess drug response in patients.

## Abstract

Parkinson's disease (PD) is a neurodegenerative disorder characterized by loss of dopaminergic neurons in the substantia nigra, and accumulation of iron and alpha-synuclein; it follows a characteristic pattern throughout the nervous system. Despite, decades of successful preclinical neuroprotective studies, no drug has then shown efficacy in clinical trials. Considering this dilemma, we have reviewed and organized solutions of varying importance that can be exclusive or additive and outline approaches to help generate successful development of neuroprotective drugs for PD: 1) select patients in which the targeted mechanism is involved in the pathological process associated with the monitoring of target engagement; 2) combine treatments that target multiple pathways; 3) establish earliest interventions and develop better prodromal biomarkers; 4) adopt rigorous methodology and specific disease-relevant designs for disease-modifying clinical trials; 5) customize drug with better brain biodistribution; 6) prioritize repurposed drugs as a first line approach; 7) adapt preclinical models to the targeted mechanisms with translational biomarkers to increase their predictive value.

## Introduction

Parkinson's disease (PD) is a complex neuropsychiatric disorder.<sup>1,2</sup> It is a progressive and topographically extensive neurodegenerative disease, with a classical pathological hallmark that involves dopaminergic neuron regulated cell death, notably in the substantia nigra pars compacta (SNpc). It is associated with iron accumulation, oxidative stress, nitrosative stress, lipid peroxidation, neuro-inflammation, glutamate excitotoxicity, mitochondrial deficits, lysosome and proteasome alteration with protein misfolding notably of alpha synuclein ( $\alpha$ -syn) with aggregates.<sup>3-5</sup>

Many preclinical studies have identified efficient therapeutic strategies that work well in animal models of PD, but so far, none of them has been confirmed to be effective in clinical trials in patients (**Figure 1**). Consequently, many pharmaceutical and biotechnology companies have been reluctant to enter or even remain in the field of PD drug development. **One conceivable fundamental problem for the repetitive failure to convert positive pre-clinical results into therapeutic success might be that PD does not consist of a single disorder, but rather, it consists of a syndrome that shares only weak biologic commonalities and thus requires a careful molecular and clinical triage.**<sup>6</sup>

Another major difficulty in developing clinical trials for neuroprotection is the fact that the brain is not accessible for *in vivo* neuronal counts, and therefore there are no tools in the clinic capable of monitoring neuroprotection. Consequently, the term "disease modifier" was introduced in the field (**Figure 2**). The concept of a disease modifying agent implies that it is able to demonstrate a tangible impact on molecular mechanisms known to be involved in the degenerative process. Currently, many of these cannot be fully demonstrated in patients due to limitations in brain accessibility, and the lack of suitable biochemical imaging markers. In this review, we identify and discuss seven current limiting factors of neuroprotective strategies and propose solutions for each of these to help develop efficient treatments aiming at reducing the rate of downward trajectory of disease progression in PD (**Figure 3**). **Importantly, these solutions are not of equal importance, some of them being exclusive and others additive.**

## Search strategy and selection criteria

To the best of our knowledge, there is no review describing the strategies required for a translational development of a treatment for neuroprotection in PD. References for this review

1  
2  
3 were identified by searches of PubMed between 1969 and July 2020. The search terms were  
4 guided by two strategies: 1) recent reviews on each topic and 2) examples to illustrate the  
5 concepts and the solutions.  
6  
7

8  
9  
10 **Challenge 1: PD is not just “heterogeneous” or “complex” but a syndrome.**

11 PD belongs to the wide range of complex multifactorial and polygenic disorders influenced  
12 both by genetic and environmental factors, and is very likely a combination of both in a large  
13 proportion of PD patients. Less than 10% of PD cases have a monogenic origin. The known  
14 causal mutations affect 15 genes and explain only about 30% of monogenic (and 3–5% of  
15 sporadic) cases.<sup>6</sup> Moreover, the monogenic forms display a variable penetrance, variable  
16 expression and a very long pre-symptomatic phase, suggesting that other causal and risk factors  
17 are involved in the pathogenesis. Unbiased genome-wide association studies (GWAS) have  
18 demonstrated a role of more common genetic variants, leading to the concept of ‘graded risk’,  
19 which is a continuum from Mendelian mutations, low frequency disease-causing mutations,  
20 and common polymorphisms with an associated strong-to-low impact on the disease expression  
21 and progression.<sup>7-11</sup> A similar level of complexity of provenance applies to our understanding  
22 of the environmental toxic causes of PD.<sup>12</sup> Exposure to pesticides have been reported to increase  
23 the risk of developing PD, especially for farmers employing organo-chloride chemicals,<sup>13-15</sup>  
24 exposure to MPTP<sup>16</sup>, and intoxication by n-hexane,<sup>17</sup> atypical French Caribbean  
25 Parkinsonism.<sup>18</sup> Noteworthy, most of these environmental compounds are inhibitors of  
26 mitochondrial complex 1, which suggests this as a specific pathway of neurodegeneration. This  
27 complicated situation might be made even more complex due to the behavioral consumption of  
28 substances during one’s lifetime that might themselves also alter PD progression. Indeed, the  
29 risk of developing PD has been shown to be lower in smokers than in non-smokers,<sup>19,20</sup> or in  
30 individuals treated by anti-inflammatory drugs such as Ibuprofen.<sup>21</sup> Consequently, it is  
31 important to consider the various etiologies and risk factors of PD on one hand whilst, on the  
32 other hand, also actively consider the positive and negative risk factors that influence the rate  
33 of disease progression. A major limitation of most neuroprotective PD clinical trials is that the  
34 precise etiology of the disease, and the prior individual environmental exposures of the patients  
35 recruited into these studies, remains unknown.

53  
54  
55

56 **Solution 1: To develop clinical trials on patients with known etiology and risk factors**

57 In a diabetic patient, no one would prescribe anti-diabetic drugs without considering the  
58 patient’s dependency on taking insulin. However, it is exactly this type of mistake we are  
59  
60

1  
2  
3 making in the field of PD by including patients with mixed etiologies in neuroprotection trials.  
4 There is now a clear need for changing the strategy and performing clinical trials on well-  
5 characterized populations of patients. Despite the small number of patients with a genetic origin  
6 of their disease, clinical trials should be developed on populations of patients with identical  
7 mutations. Furthermore, the diagnosis of PD should be validated by combining specific clinical  
8 criteria (MDS)<sup>22,23</sup> and imaging of dopamine depletion for inclusion criteria of de novo  
9 patients.<sup>24,25</sup> This is especially important in carriers of PD causative mutations, as they might  
10 still be in a presymptomatic stage of the disease. Furthermore, because in patients with identical  
11 mutations the clinical and pathological expression of the disease might vary,<sup>7,9</sup> selecting more  
12 homogenous subpopulations according to the rate of progression of the disease and prognosis  
13 factors should be the gold standard. Indeed, in de novo patients, probable predictors of more  
14 rapid motor decline and disability could be used - such as higher age at onset, baseline motor  
15 impairment with higher postural instability, and gait disorders score (non-tremor dominant  
16 subtype), cognitive impairment and depression.<sup>26,27</sup> However, specific criteria validated with a  
17 rigorous approach on large cohorts are still lacking.<sup>28</sup>

18

20  
21  
22  
23  
24  
25  
26  
27  
28  
29  
30  
31 Even patients with exactly the same mutation can display different phenotypes. This is very  
32 likely due to different environmental exposures during life, as well as incomplete penetrance.  
33 Thus, the concept of 'graded risk' developed from genetic research needs to associate the  
34 environment causes and risk factors. The genetic approaches that identify very rare causative  
35 mutations underlying monogenic forms and common variants with small effects need to be  
36 associated with questionnaires and biological samples for environmental factors,<sup>12-19</sup> the co-  
37 morbidity, and the antiparkinsonian and other treatments. By comparing large cohorts of  
38 patients and controls, machine learning and deep learning might allow stratifying the various  
39 subpopulations according to the risk factors of developing PD with omics and epigenetic  
40 analyses to develop the future biomarkers of patient stratification for upcoming trials.<sup>8</sup> The  
41 same strategy needs to be developed on longitudinal cohorts of patients with respect to the  
42 accurate selection of trial end points of disease progression, or time to chosen milestones, or  
43 the novel weighted composite endpoint (PDCORE)<sup>29</sup>.

44  
45  
46  
47  
48  
49  
50  
51  
52  
53  
54 Altogether, a better characterization of the patients in terms of the causes and the factors of their  
55 disease progression will lead to a better stratification and to reduce patient variability in order  
56 to improve the statistical accuracy of the outcomes and end-points measured (**Figure 3**).

57  
58  
59 **Challenge 2: Targeting single pharmacological pathways is not efficient**

1  
2  
3 The mechanisms leading to neurodegeneration in PD include multiple pathways.<sup>3-5</sup> Ultimately,  
4 neurons die by regulated cell death. However, 14 separate types of cell death have now been  
5 defined.<sup>55</sup> Apoptosis, ferroptosis, necroptosis, autophagy and parthanatosi (target of rapamycin  
6 (mTOR) poly (ADP-ribose) (PAR) polymerase-1 (PARP-1)) appear to be particularly relevant  
7 for PD.<sup>56-59</sup> Yet, further studies are required to better characterize the exact types of cell death  
8 that are most relevant in PD neurodegeneration. Importantly, recent research in cancer has  
9 demonstrated that, while there are distinct individual forms of cell death involved, they also  
10 display key connections between them, notably between ferroptosis, autophagy and  
11 parthanatosi.<sup>60,61</sup> In addition, whether these molecular and cellular interactions represent a  
12 cause or a consequence of neurodegeneration in PD still needs clarification. An important issue  
13 for developing efficient neuroprotective trials is to determine whether the molecular changes  
14 involved actually belong to the same molecular pathways or instead to parallel pathways (i.e.  
15 different pathways). Of course, a broad action on several pathways will largely increase the  
16 chance of success.

22  
23  
24  
25  
26  
27  
28  
29 **Solution 2: Identify all PD-relevant pathways of cell death and combine treatments that**  
30 **target multiple pathways**

31  
32 Identifying the interactions between the molecular and cellular changes seen in PD is a key  
33 requirement in terms of informing how best to establish robust neuroprotection. Of course, if  
34 they belong to the same pathway blocking the deleterious mechanism, whether upstream or  
35 downstream to these molecular targets, this will result in the same protective effect and a single  
36 drug might therefore likely be highly efficient. On the other hand, if they belong to parallel  
37 pathways, then blocking one of these will not result in neuroprotection since the deleterious  
38 effects of the other pathway will still contribute to the neurodegenerative process. It has been  
39 exemplified in experimental models of PD that mitochondrial complex 1 deficiency and  
40 proteasome dysfunction belong to parallel pathways.<sup>62</sup> Thus, if this is similarly true in human  
41 pathology, then disease-modifying clinical trials will require a combination of two or more  
42 drugs, and thereby targeting multiple pathways involved in neurodegeneration. Alternately, one  
43 might consider using drugs with a pleiotropic action, or using an appropriate combination of  
44 drugs. Yet, drug agencies still require proof of efficacy of each single drug – as monotherapies  
45 - before approving the development of any combinations of these drugs. But such a multi-drug  
46 strategy has already been proven to be highly successful in the fields of cancer, HIV and  
47 tuberculosis. Future neuroprotective strategies in PD should similarly test combinations of  
48 drugs selected on the basis of the various relevant mechanisms of cell death in any given  
49

2  
3 subtype of PD. This strategy has recently started in amyotrophic lateral sclerosis with a  
4 combination of two drugs already in use (sodium phenylbutyrate and tauroursodeoxycholic  
5 acid).<sup>63</sup> However, this strategy will not overcome the problem of whether any of the pathways  
6 targeted are truly at play in the population recruited for those trials.  
7  
8  
9

### 11 **Challenge 3: Neuroprotective interventions are initiated too late in the course of the** 12 **disease**

13  
14  
15 Most clinical trials are started a few years after the onset of symptoms, partly to ensure all  
16 enrolled patients have a reliable diagnosis of PD. Yet, imaging studies of dopaminergic markers  
17 have estimated there is a preclinical period of 15 to 20 years in younger, and 10 years in older,  
18 PD patients.<sup>30</sup> By the time motor symptoms appear, patients have, lost 80 percent of their striatal  
19 dopamine, corresponding to 50% loss of dopaminergic neurons in the substantia nigra.<sup>31,32</sup>  
20 Additionally, neuropathological examinations have, years before the SNpc is affected, shown  
21 lesions in the olfactory bulb, mesenteric plexus, brainstem including locus coeruleus, and raphe  
22 nucleus.<sup>16,33</sup> Finally, the neurodegenerative process might by itself engage a self-perpetuating  
23 phenomenon as shown in the human subjects intoxicated by MPTP. Thus, it is clear that late  
24 therapeutic intervention obviously decreases the chance of success.  
25

### 34 **Solution 3: To establish early interventions and develop better prodromal biomarkers**

35  
36 The prodromal phase is theoretically the best period to start any neuroprotective treatment, and  
37 it should ideally be initiated before any important damage of the nigro-striatal pathway has  
38 occurred corresponding to the first stages (1 and 2) of Braak's classification.<sup>33</sup> However, there  
39 are two major limitations. i) The spectrum of symptoms during these early Braak's stages  
40 remains complex and very variable among patients.<sup>34,35</sup> ii) Some individuals recruited during  
41 the prodromal phase may not express the disease, or may only develop it very late. This calls  
42 for a search of better diagnosis biomarkers (wet, dry, wearable) during the prodromal phase of  
43 the disease, and incorporating likelihood ratios with age and gender (of developing overt PD),  
44 and improved predictive algorithms generated by big data approaches to predict the likelihood  
45 of progression into the symptomatic phase.<sup>35-38</sup>  
46  
47  
48  
49  
50  
51  
52  
53

54  
55 Until now de novo patients have constituted the best population for neuroprotective trials, with  
56 the aim that the remaining dopaminergic neurons can be saved.<sup>39-42</sup> Furthermore, at this stage,  
57 there is no interference of dopaminergic treatment on the analysis of any neuroprotective effect.  
58 However, it is difficult to recruit de novo patients for several reasons. 1) There is a risk of  
59  
60

1  
2  
3 including atypical forms and lack of dopamine depletion. 2) There is a higher patient dropout  
4 rate because patients are stressed, or in denial, after receiving their diagnosis, and may poorly  
5 tolerate the lack of symptomatic treatment.<sup>42-45</sup> Another alternative is to perform the trials on  
6 early PD patients (within the first 3 years after diagnosis) because they receive a stable,  
7 moderate-dose regimen of dopaminergic drugs and could still benefit from an intervention that  
8 would reduce the rate of disease progression. Furthermore, these patients are easy to recruit and  
9 allow studying the interactions between the neuroprotective compound and dopamine agonists  
10 and/or L-dopa.<sup>42-45</sup>

11  
12  
13  
14  
15  
16  
17  
18  
19 The ideal population of patients to include in neuroprotective trials are those characterized by  
20 a genetic trait, or by a biomarker that would confirm the diagnosis during the presymptomatic  
21 phase **and that can demonstrate the molecular susceptibility to the mechanism of the drug to**  
22 **which it is exposed.** Asymptomatic carriers of mutations causative of PD represent the best  
23 population to study. Yet, in such patients, the onset of the symptoms is very difficult to predict.  
24 One strategy would consist of performing neuroprotective trials in these patients a few years  
25 before the mean age of onset in such a specific population. The read-out of these types of  
26 neuroprotective studies would then be the “delayed time to transition” to the symptomatic  
27 phase. Yet, such patients are relatively rare and inclusion difficulties might prevent extensive  
28 clinical trials unless run as a global effort. Furthermore, because of the variability in the duration  
29 of the asymptomatic phase due to variable penetrance of the genes involved, such initiatives  
30 might also require long study durations, thereby increasing their cost.<sup>6,42-45</sup>

31  
32  
33  
34  
35  
36  
37  
38  
39  
40  
41 Because of the difficulties in performing clinical trials in inherited forms of PD, neuroprotective  
42 approaches should also be tested in sporadic cases. To do this, there is a need for diagnostic  
43 biomarkers during the prodromal phase of the disease. Many studies have attempted to identify  
44 such wet and dry biomarkers.<sup>6,38,40,42,43,45-48</sup> Among those candidates,  $\alpha$ -synuclein ( $\alpha$ -syn) is  
45 regarded by many as the most promising.<sup>6,33,41</sup> However, PD is usually associated with  
46 abnormal accumulation of several other types of misfolded proteins, notably  $\beta$ -amyloid and tau,  
47 which co-occur with  $\alpha$ -syn.<sup>6,33,41</sup> Moreover, Lewy pathology is not necessarily found in all  
48 forms of PD (e.g. some leucine-rich repeat kinase 2 (LRRK2) patients, and most of the Parkin-  
49 related cases).<sup>6,48</sup> Furthermore, even in cases with clear synucleinopathies, there is no dose-  
50 dependent correlation between Lewy pathology, cell loss and clinical features.<sup>49,50</sup>  
51 Consequently,  $\alpha$ -syn represents a convenient pathologic biomarker but may not be pathogenic  
52 with the exception of  $\alpha$ -syn-related genetic PD patient subtypes.<sup>51-54</sup> Moreover,  $\alpha$ -syn

determination in fluids or peripheral tissues cannot be the sole surrogate biomarker of PD because its concentration is modified by complex physiopathological responses within the body, as well as being modified by the consequences of PD neurodegeneration. Further studies are required to analyze the dynamic expression and deposition of  $\alpha$ -syn during PD disease progression, ideally using a translational approach.

#### **Challenge 4: The methodology of clinical trials is not adapted to progressive long-term neurodegeneration**

The design of disease-modifying, neuroprotective clinical trials in PD patients is very challenging for several reasons. First, there is no reference drug, nor any clinical trial design, that has ever shown efficiency for neuroprotection. This might be due to the lack of efficacy of the tested drugs and/or from poor clinical trial designs, or both. This problem is even more complex in PD because the tested medications might have both a symptomatic and a neuroprotective effect. Second, biomarkers of neuroprotection are still lacking and it is therefore difficult to determine on rational scientific grounds whether or not the drug being tested is actually reaching its biological target and is thereby having a positive effect at a cellular level. Thus, clinical trials mostly rely on clinical outcomes. However, the clinical symptoms are, themselves, not very sensitive to be able to demonstrate meaningful change since they do not progress rapidly enough to measure accurately, at least not over the study durations, typically 1 year, chosen for most neuroprotective clinical trials in PD patients. Third, even with well-validated scales such as UPDRS, drug testing of putative neuroprotective agents is not typically performed in a real-life environment. Finally, the global handicap (i.e. motor, cognitive and behavior), also including the rather more variable non-motor symptoms, needs to be considered. All of this, calls for new designs of neuroprotection trials in PD.

#### **Solution 4: To adopt rigorous methodology and specific disease-relevant designs for PD neuroprotective clinical trials**

It is clear that greater attention must be paid in selecting the most appropriate clinical trial design, with either an adaptation of a well-tested design, or new approach depending on any suspected possibility or likelihood that the neuroprotective drug under investigation may also have a concomitant symptomatic effect.<sup>6,42-45</sup> (Figure 3) Adaptive trials have been also proposed as a version of the responder trial.<sup>71</sup> A first discovery phase includes a broad population with several subtypes followed by a validation phase considering only the best patient responders. Master protocols, including “basket trials”, “umbrella trials”, and “platform

1  
2  
3 trials”, use a trial network with shared infrastructure and are designed with multiple sub-studies  
4 to evaluate one or more investigational drugs in one or more disease subtypes.<sup>72,73</sup> Following  
5 the same idea, multi-arm, multi-stage (MAMS) trials have been recently proposed to test many  
6 potential therapies currently in the pipeline in parallel (multi-arm), transitioning seamlessly  
7 through various phases (multi-stage), i.e., from a phase II safety and efficacy study to a phase  
8 III trial, with the help of a platform.<sup>74</sup> While they are attractive, they come from the oncology  
9 field where the simultaneous therapeutic use of multiple drugs is already validated and accepted  
10 by regulatory authorities, which is far from the current case for PD.

11  
12 The demonstration of the reduction of an already slow disease progression is very challenging  
13 since it requires a long-term study during which the symptomatic dopaminergic requirements  
14 of patients are frequently changing, and this can greatly confuse the interpretation of  
15 neuroprotective results. Regarding the duration of the trial, if a symptomatic treatment is not  
16 introduced or modified, a period between 6 to 12 months represents a reasonable and practical  
17 compromise between having sufficient time to observe a neuroprotective effect and the  
18 relatively limited number of patient dropouts set against an attrition of study subjects that  
19 inevitably continues to increase over longer trial durations. For example, a study duration of 6  
20 months in de novo patients was associated with a drop-out rate of 10-15% in the ADAGIO  
21 trial.<sup>75</sup> Conversely, a 9-month period would have a greater chance of clinical success but at the  
22 expense of a higher drop-out rate in de novo patients.<sup>45</sup>

23  
24 The current MDS-UPDRS clinical scales are not designed to assess subtle modifications of  
25 disease progression. This low sensitivity to monitor change requires a very large population of  
26 patients to be followed for long periods of time, and this is very challenging for Phase II trial  
27 purposes. Using a biomarker as a primary outcome measure is an interesting alternative for an  
28 early phase II study. Objective and continuous measures offer a different perspective, with  
29 wearable technologies provide specific and rigorous quantification that could become efficient  
30 biomarkers of motor handicap in real life spanning over several days, such as, connected  
31 actimetry<sup>76</sup> and connected soles for a continuous recording of gait and balance.

### 32 33 **Challenge 5: Targeting the central nervous system (CNS) represents a pharmacological** 34 **challenge**

35  
36 Another major challenge relates to the poor blood-brain-barrier (BBB) penetration of many  
37 candidate neuroprotective drugs. The competitive and variable drug penetration in the brain  
38 parenchyma leads to low and unpredictable bio-distribution in the CNS with additional  
39  
40  
41  
42  
43  
44  
45  
46  
47

55  
56  
57  
58  
59  
60

1  
2  
3 confounding interference from dietary foods and drug interactions etc. Furthermore, for most  
4 of the drugs there is no measurement of its concentration in the brain parenchyma, nor of its  
5 engagement with its biological target in neurons. Thus, clinicians currently only rely on clinical  
6 scales or, in the best cases, also on various available imaging parameters of the brain.  
7  
8  
9

10  
11 The issue of BBB drug penetration might also be challenging due to blood vessel modifications  
12 associated with the disease process or the medication<sup>77,78</sup>  
13  
14  
15

### 16 17 **Solution 5: To customize drug with better and more selective brain accessibility**

18 Pharmacokinetic studies with drug concentration measurements should be associated in both  
19 preclinical and clinical studies. Yet, this is complex because cerebrospinal fluid (CSF) is not  
20 accessible on a repetitive basis and only gives a biased measurement of the drug concentration  
21 in the brain region targeted by the drug. Furthermore, sampling of both CSF and blood as a  
22 function of time after administration provides an estimate the precision of which will depend  
23 on the number of samples over time. The association of brain tissue and clinical measures -  
24 respectively in both the experimental models and the patients - should ideally allow the  
25 establishment of an algorithm to help select the best dose and regimen in humans.  
26  
27  
28  
29  
30  
31  
32  
33

34 Another need is to improve drug penetration into the brain by customizing drugs with better  
35 penetration characteristics, or by developing prodrugs that will easily cross the BBB. Indeed,  
36 oral administration is obviously the easiest, but not the best, method of drug delivery for brain  
37 diseases. Transnasal delivery is also noninvasive and easy to operate and should be considered  
38 for intermittent administration of small molecules or small volumes of drug.<sup>79</sup> Only small and  
39 lipophilic drugs can readily penetrate into the brain. In the situation where a very effective  
40 neuroprotective drug poorly penetrates the BBB, then several options might be usefully  
41 considered to help improve its brain penetration. The first option for small molecules is to  
42 increase their lipidation, or to reduce their size, keeping only the active neuroprotective  
43 fragment. Another interesting option is to use a lipophilic prodrug.<sup>80,81</sup> Nanoparticles represent  
44 another chemical modification to increase BBB permeability (**Figure 3**).<sup>82,83</sup>  
45  
46  
47  
48  
49  
50  
51  
52

53 If, despite chemical modification, the drug does not penetrate into the brain parenchyma then  
54 instead, direct delivery in the brain might be considered.<sup>84</sup> The procedure involving intrathecal  
55 administration of baclofen or painkillers has been reported to be effective, reversible, and safe  
56 in thousands of patients.<sup>85</sup> The safety of brain infusion of growth factors has also generated  
57 promising results despite a lack of efficacy for neuroprotection.<sup>86</sup> With such procedures, high  
58  
59  
60

1  
2  
3 local drug and personalized concentrations can be achieved with no or minimal systemic  
4 adverse events.  
5  
6

7  
8 Developments using physical, chemical and biological methods to open the BBB have also  
9 emerged recently. For example, focused ultrasound (FUS) has been shown to be safe and very  
10 efficient. Such approaches represent an interesting alternative for intermittent administration of  
11 drugs with long lasting effects.<sup>87,88</sup> Co-administration of or substances acting on the efflux  
12 carriers, and transporters, can also theoretically increase drug penetration.<sup>84</sup>  
13  
14  
15  
16  
17

### 18 **Challenge 6: Neuroprotection represents a very long and risky drug development**

19 Developing a new drug is always very long (an average of 14.2 years), very expensive (US  
20 \$802 million) and challenging.<sup>89</sup>  
21  
22  
23  
24

### 25 **Solution 6: To reduce the risk of drug development for PD**

26 Additional safeguards need to be developed with combined efforts both from academic partners  
27 and the drug industry. Prioritizing the development of repurposed drugs represents an attractive  
28 approach for neuroprotection in PD. Drugs already on the market for other therapeutic  
29 indications have the advantage of being already used for humans, and helpfully already have a  
30 well-known safety profile. Because of the extensive experience with these compounds they are  
31 generally also straightforward to test in preclinical models. Generally, their pharmacokinetic  
32 and pharmacodynamic characteristics are known, but the issues of brain penetration and  
33 adaptation of the dosage to the CNS might not be trivial. In terms of intellectual property, a new  
34 patent of an old drug for a new indication or formulae typically allows increasing the time for  
35 development for use in another indication. Target validation and lead molecule optimization  
36 can then be developed based upon this safe, first-in-class, repurposed drug.  
37  
38

39 Another way of reducing the risk for drug development in neuroprotection is based on the fact  
40 that a few drugs may have shown efficacy in animals, and then also shown encouraging  
41 results in humans, but were subsequently abandoned because of their toxicity in a very small  
42 number of patients. Yet, even if a drug does not have an ideal safety profile, rigorous  
43 monitoring can allow testing it in clinical trials. Deferiprone is currently being clinically  
44 assessed for conservative iron chelation despite a rare risk of agranulocytosis (<0.8%).<sup>90,91</sup>  
45  
46  
47  
48  
49  
50  
51  
52  
53  
54  
55  
56

### 57 **Challenge 7: Animal models of PD are not predictive of clinical efficacy**

1  
2  
3 No molecule that has demonstrated positive *in vitro*, and *in vivo*, effects on neuroprotection  
4 has displayed any neuroprotective effect in clinical trials.<sup>42,64</sup>  
5  
6  
7

8 **Solution 7: To adapt preclinical models of PD and research design to the clinical**  
9 **situation**

10 One of the reasons for the lack of predictive value of any of the PD animal models is the fact  
11 that these models cannot recapitulate the clinical situation. Animal models can inform about  
12 mechanisms of therapy but not about patient selection for that therapy. This is why one should  
13 associate, in a translational manner, dry and wet biomarkers of the targeted mechanisms both  
14 in the models, and in humans, to ascertain neuroprotection.  
15  
16  
17  
18  
19

20  
21  
22 The prediction of neuroprotection requires human, non-oncogenic, cell models including  
23 LUHMES, primary dopaminergic neuron culture, patient-derived Inducible Pluripotent Stem  
24 cells and three-dimensional brain organoids<sup>65</sup>.  
25  
26  
27

28  
29 Several *in vivo* models have been generated through neurotoxin-based or genetic-based  
30 approaches in rodents, or non-human primates, to demonstrate and validate neuroprotection.  
31 Neurotoxin-induced models reproduce some of the key molecular alterations such as complex  
32 1 deficiency, or proteasomal dysfunction. Chemicals such as 6-hydroxydopamine, MPTP,  
33 rotenone, annonacine, and paraquat are mainly used to generate these types of PD models.  
34 Protein accumulation can be generated via overexpression of  $\alpha$ -syn. In addition, protein  
35 aggregation pathology can be triggered by inoculating preformed fibrils of  $\alpha$ -syn in the brain.<sup>66</sup>  
36 Yet, a limitation of these models is that not all of the molecular changes seen in PD actually  
37 coexist in a single model. It may be useful, to increase the prediction by associating different  
38 experimentations in different *in vivo* models (toxin and genetic hits), to reproduce far better the  
39 full pathological process as typically seen in PD.<sup>66</sup>  
40  
41  
42  
43  
44  
45  
46  
47  
48

49 Another important issue of neuroprotection trials is that, even for a same mutation, the clinical  
50 phenotypes of the patients recruited into a trial do vary considerably. Preclinical  
51 neuroprotection studies should therefore be performed using animals of mixed genetic  
52 backgrounds, and not on inbred animals from an identical genetic provenance, but this may  
53 necessitate an increase in the required number of animals to achieve statistical significance.  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 The immune status of animals is also important to monitor because neuroinflammatory  
4 processes also participate to neuronal degeneration. Indeed, most preclinical studies are  
5 performed on animals housed in a sterile environment, but PD patients in their daily lives are  
6 in constant contact with multiple immune stimulating agents. Lipopolysaccharide, a bacterial  
7 membrane molecule well known for its immune stimulating properties, increases the sensibility  
8 to parkinsonian toxins in rodents.<sup>67</sup> Such a phenomenon might even start very early during life  
9 as offspring of pregnant rats injected with LPS are also more sensitive to parkinsonian toxins.<sup>67</sup>  
10 One should thus consider monitoring carefully the immune status of the animals or perhaps  
11 even house the animals in standard non-SFP facilities.  
12  
13  
14  
15  
16  
17  
18  
19

20 Because PD is in most cases associated with aging, preclinical studies should include old  
21 animals. Indeed, elderly humans, and old animals, show less neuronal plasticity<sup>68</sup> a lower level  
22 of dopamine metabolism<sup>69</sup> and a higher iron content (which increases the pro-oxidant status<sup>70</sup>),  
23 and they also display considerably different dose-related effects to drugs given. PD is more  
24 prevalent in men, but both genders need to be accurately assessed because huge differences  
25 between them can be observed in terms of dose effects and neuronal degeneration.  
26  
27  
28  
29  
30  
31

32 The chronicity (months or even years) both of the degenerative process, and of the treatment  
33 regimen given, as well as the time at which the treatment is first introduced (ideally at time of  
34 the onset of symptoms) should be accurately reproduced in animal models.  
35  
36  
37  
38

39 Finally, good practice standards should be used in preclinical studies just as is the case in the  
40 clinical studies (**Figure 3**). Such standards are costly and will dramatically reduce the number  
41 of studies but will undoubtedly increase their predictability.  
42  
43  
44  
45

## 46 **Conclusion**

47 We have described a number of critical hurdles that are currently hampering progress towards  
48 bringing effective neuroprotective therapeutic approaches to slow disease progression in  
49 patients with Parkinson's disease, which arguably represents the greatest unmet need in this  
50 therapeutic area. We do not believe any of these hurdles are intractable and, especially  
51 considering the wealth of promising new neuroprotective approaches that are currently  
52 emerging, we have therefore outlined **and organized exclusive or additive solutions of varying**  
53 **importance** to help generate successful development of neuroprotective drugs for PD solutions  
54 and approaches to help overcome most or all of these hurdles.

## Legends

### **Figure 1: Past and current therapeutic strategies illustrating the need of biomarkers of target engagements**

Main physiopathological mechanisms (orange boxes) with complex and multiple interplays (arrows to show that they are in fact all connected), failed past therapeutic strategies (light blue boxes), strategies currently in clinical trials (dark blue boxes). (sources:<sup>42,92</sup> and [www.clinicaltrials.gov](http://www.clinicaltrials.gov)). None of the past and failed trials matched the therapies tested with the suitable molecular biology of the intended recipients. Thus, there is an urgent need of biomarkers that can demonstrate the molecular susceptibility to the mechanism of the drugs in order to validate target engagement and to assess drug response in patients.

**Figure 2: Vocabulary of treatment modalities** according to (a) the impact on the neuronal count in preclinical models and (b) on the clinical handicap progression in patients.

### **Figure 3: Seven solutions**

Organization of seven interconnected solutions of varying importance that can be exclusive or additive and outline approaches to help generate successful development of efficient treatments aiming at reducing the rate of downward trajectory of disease progression.

**Abbreviations:** PD: Parkinson's disease
