Abstract. We present the results of methane profiling in the lower troposphere using LILAS Raman lidar from the Lille University observatory platform (France). The lidar is based on a frequency-tripled Nd:YAG laser, and nighttime profiling up to 4000 with 100 m height resolution is possible for methane. Agreement between the measured photon-counting rate in the CH₄ Raman channel in the free troposphere and numerical simulations for a typical CH₄ background mixing ratio (2 ppm) confirms that CH₄ Raman scattering is detected. The mixing ratio is calculated from the ratio of methane (395.7 nm) and nitrogen (386.7 nm) Raman backscatters, and within the planetary boundary layer, an increase of the CH₄ mixing ratio, up to a factor of 2, is observed. Different possible interfering factors, such as leakage of the elastic signal and aerosol fluorescence, have been taken into consideration. Tests using backscattering from clouds confirmed that the filters in the Raman channel provide sufficient rejection of elastic scattering. The measured methane profiles do not correlate with aerosol backscattering, which corroborates the hypothesis that, in the planetary boundary layer, not aerosol fluorescence but CH₄ is observed. However, the fluorescence contribution cannot be completely excluded and, for future measurements, we plan to install an additional control channel close to 393 nm, where no strong Raman lines exist and only fluorescence can be observed.

1 Introduction

Raman spectroscopy is a powerful technique for identification of different gases in the atmosphere and for the estimation of their concentration (Weber, 1979), which can be used in conjunction with lidar technology (Inaba and Kobayasi, 1972). An example of such synergy is the Raman lidar for water vapor monitoring (Whiteman et al., 1992). For optimum application of the Raman technique, the gas of interest should be abundant in the atmosphere, possess a large scattering cross section and have a Raman spectrum that is isolated from potential interfering species. Detection of water vapor with Raman spectroscopy satisfies all of these conditions and has become a very popular application of lidar (e.g., Whiteman et al., 2007, and references therein). Besides water vapor, Raman lidar profiling of carbon dioxide (Ansmann et al., 1992; Whiteman et al., 2007; Zhao et al., 2008), as well as quartz crystals in dust layers (Müller et al., 2010), has been reported.

Methane is currently the second most important greenhouse gas (after carbon dioxide) of anthropogenic origin (IPCC, 2013). Methane is emitted from a variety of natural and anthropogenic sources (e.g., Baray et al., 2018; Kavitha et al., 2016, and references therein) and on a per-molecule basis, methane is about 30 times more effective a greenhouse gas than carbon dioxide (Etminan et al., 2016). Global information about the CH₄ column concentration is available from satellite observations with, for example, the SCIAMACHY sensor on board the ENVISAT satellite (Bovensmann et al., 1999) or the TANSO-FTS sensor on board the

GOSAT satellite (Kuze et al., 2009). Passive observations, however, can be influenced by the presence of aerosol layers or thin ice clouds. The lack of precise global measurements of atmospheric methane initiated, in particular, the upcoming MERLIN mission, offering integrated path differential absorption space-borne lidar (<https://earth.esa.int/web/eoportal/satellite-missions/m/merlin>, last access: 5 December 2018), which should provide unprecedented accuracy of CH₄ column values. Still, the integrated path technique does not provide the profile of the methane mixing ratio, which can vary significantly in the lower troposphere.

Today, it is well established that, in the free troposphere the CH₄ mixing ratio is about 2 ppm, while inside the planetary boundary layer (PBL), the mixing ratio can be increased in the vicinity of methane sources (Baray et al., 2018). Such enhancement up to 4 ppm was observed, for example, in the airborne measurements over oil sands (Baray et al., 2018). At low altitudes, the methane concentration depends on the PBL dynamics, so it is important to profile the methane mixing ratio simultaneously with the PBL parameters such as PBL height and aerosol backscattering. Profiling of the PBL is commonly done by aerosol lidars (Kovalev and Eichinger, 2004), while for methane profiling either the differential absorption (DIAL) or Raman lidars can be used.

Existing DIAL systems for measuring methane are based on tunable parametric laser sources and operate in the short-wave infrared (SWIR) spectral range between 1.65 and 2.3 μm , where methane has strong absorption lines (Refaat et al., 2013; Riris et al., 2017). Due to low Rayleigh scattering in the SWIR region, methane profiling using the DIAL technique is possible only inside regions containing significant amounts of aerosol. Raman lidars, by contrast, use standard off-the-shelf tripled Nd:YAG lasers, are relatively simple in design and can be operated in aerosol-free atmosphere. The methane molecule is quite suitable for Raman detection. The vibrational Raman line at 2914 cm^{-1} is well isolated and has the scattering cross section about 8 times higher than that of nitrogen (Weber, 1979). The main difficulties of CH₄ Raman detection are related to its low background atmospheric concentration. The first attempts to implement CH₄ Raman spectroscopy in lidars go back to the 1980s. Raman lidar was used for monitoring methane plumes with relative CH₄ volume concentrations of about 2 % (Houston et al., 1986). Monitoring of the background CH₄ concentrations in the troposphere with airborne Raman lidar was reported by Heaps and Burris (1996). In both cases powerful excimer lasers (XeCl and XeF) were used. However, the wideband radiation of excimer lasers requires the use of wideband interference filters in Raman channel, which, in turn, increases the sky background noise and possible contribution of aerosol fluorescence. Wideband detection also creates an additional complication related to interference from the oxygen Raman overtone (second Stokes shift) (Heaps and Burris, 1996). Significant progress in the development of the interference filters, detectors and laser sources during the last 2 decades now pro-

vides the opportunity to develop the CH₄ Raman lidar based on a relatively compact tripled Nd:YAG laser. For narrow-band 354.7 nm laser radiation the vibrational Raman line of methane is at 395.7 nm, while the oxygen Raman overtone (3089 cm^{-1}) is at 398.4 nm, which can be rejected by the interference filter.

In our paper we present the first results of methane profiling in the lower troposphere using LILAS Raman lidar from the Lille University observatory platform (Hauts-de-France region, France). The observations demonstrate that inside the PBL, the CH₄ mixing ratio may exceed the background concentration levels by up to a factor of 2. Enhancement of the CH₄ mixing ratio in weak elevated aerosol layers was also detected.

2 Experimental setup

The experiments described here were performed using LILAS – multiwavelength Mie–Raman lidar from Lille University (Veselovskii et al., 2016). The lidar is based on a tripled Nd:YAG laser with a 20 Hz repetition rate and pulse energy of 70 mJ at 355 nm. The backscattered light is collected by a 40 cm aperture Newtonian telescope. The outputs of the detectors are recorded at 7.5 m range resolution using Licel transient recorders that incorporate both analog and photon-counting electronics. The full geometrical overlap of the laser beam and the telescope field of view (FOV) is achieved at approximately 1000 m height using a 0.75 mrad FOV. In its usual configuration, LILAS allows the detection of three elastic backscattered signals (355, 532, 1064 nm), a rotational Raman signal from N₂ and O₂ molecules at approximately 530 nm (Veselovskii et al., 2015), and vibrational nitrogen and water vapor Raman signals at 387 and 408 nm. To take the CH₄ measurements shown in this paper, we modified the water vapor channel (408 nm interference filter was replaced by the methane filter centered at 395.7 nm). The dichroic mirror in the receiver did not provide an efficient selection of the methane (395.7 nm) Raman component, so it was replaced by the mirror with high reflectance at 395.7 nm. Only a small portion of the 387 nm component was transmitted to the nitrogen channel, while more than 95 % of the 395.7 nm signal was reflected to the methane channel. Through comparing nitrogen Raman backscatter intensity before and after the modification we find that the sensitivity of the 387 nm channel was degraded by a factor of 185. The strength of the nitrogen Raman signal, though low, was sufficient for the purpose of our experiment.

The Alluxa interference filter in the methane Raman channel has a bandwidth of 0.3 nm with peak transmission greater than 80 %. The corresponding transmission curve, simulated by the manufacturer in the 300–550 nm range, is shown in Fig. 1. Suppression of 355 and 532 nm radiation is specified to be greater than 12 orders of magnitude. The Raman-scattering cross section of methane is about 8 times higher

Figure 1. Simulated transmission curve of the methane filter provided by Alluxa.

than that of nitrogen, so for a 2 ppm methane concentration the ratio of intensities of Raman nitrogen to methane scattering is about 6×10^4 . Thus, not only should the elastic backscatter components of the signal be suppressed sufficiently, but so should the nitrogen and oxygen Stokes and anti-Stokes Raman lines. To eliminate the possible contribution of rotational anti-Stokes lines, the interference filter was combined with a notch filter, providing an additional OD4 blocking in the 348–360 nm range. The contribution of the vibrational anti-Stokes lines is the most significant for oxygen (336.2 nm), where the corresponding intensity is about 20 times the intensity of CH₄ line. The filter suppression at 336.2 nm is about OD9, which is sufficient to block the anti-Stokes line contribution.

The intensity of the oxygen overtone (398.4 nm) is approximately 3 times the intensity of the methane line (Heaps and Burris, 1996), while the filter manufacturer specifies the suppression at 398.4 nm to be above OD10; hence the contribution of the oxygen overtone is negligible. To verify that no 532 nm backscatter or corresponding Raman lines leak into the methane channel, during the initial test phase a UV glass filter with transmission of less than 5% in the 500–750 nm range was also added to the methane channel. No noticeable changes in CH₄ Raman signals were discovered with this additional blocking filter in place. The transmission curve in Fig. 1 shows an increase in the 450–480 nm range, where aerosol fluorescence may occur (Sugimoto et al., 2012; Reichardt et al., 2017), with maximal transmission of 4×10^{-4} % at 455 nm. The dichroic mirrors in the detection module provide additional suppression of factor 20 at this wavelength, so total suppression of fluorescence signal at 455 nm is greater than 4×10^6 . All presented Raman methane measurements were taken in the photon-counting mode and at night only.

Table 1. Raman frequency shift for H₂O, CO₂ and CH₄ molecules and their scattering cross sections normalized to the cross section of nitrogen. Results are given for an excitation wavelength of 337 nm (Weber, 1979). Typical background-gas mixing ratios n_x in the low troposphere and the product $n_x \times \frac{\sigma_x}{\sigma_{N_2}}$ are also given.

Molecule	Frequency (cm ⁻¹)	$\frac{\sigma_x}{\sigma_{N_2}}$	Typical values of n_x (ppm)	$n_x \times \frac{\sigma_x}{\sigma_{N_2}}$ (ppm)
H ₂ O	3657	3.1	3×10^3	$\sim 10^4$
CO ₂	1285	0.8	400	320
CH ₄	2914	8.2	2	16.4

3 Numerical simulation

Numerical simulation was performed to estimate the power of the Raman backscatter for the background methane mixing ratio. The lidar equation describing the number of detected photons N_x^{ph} , scattered by molecule x at distance z due to a single laser pulse can be written as follows:

$$N_x^{\text{ph}}(z) = O(z) A_x \frac{E}{h\nu} \Delta z \frac{S}{z^2} N_x \sigma_x \exp \left\{ - \int_0^z (\alpha_L^a + \alpha_L^m + \alpha_x^a + \alpha_x^m) dz' \right\}. \quad (1)$$

Here $O(z)$ is the geometrical overlap factor, A_x is an efficiency factor, including the transmission of the optics and the quantum efficiency of the detectors. E and $h\nu$ are the laser pulse and the photon energies, Δz is range resolution, S is the receiving telescope area, N_x is the number concentration of molecule x and σ_x is the differential Raman-scattering cross section of molecule x , α is the extinction coefficient, where superscript “a” and “m” indicate aerosol and molecular contributions. Subscript “L” and “x” correspond to the laser wavelength λ_L and to the wavelength of Raman backscatter λ_x .

Table 1 shows the parameters of H₂O, CO₂ and CH₄ molecules, such as Raman frequency shift and Raman differential scattering cross section σ_x , normalized to the cross section of nitrogen σ_{N_2} . Results are presented for an excitation wavelength of 337 nm based on Weber (1979). The table also provides typical concentrations of gases in the troposphere. The efficiency of detection of molecule x is determined by the factor $n_x \times \frac{\sigma_x}{\sigma_{N_2}}$ (n_x is the molecule x mixing ratio), which is approximately 10^4 for the H₂O molecule and about 320 for CO₂. However, for CH₄ this factor is about 20 times lower than for CO₂, so detection of the methane background concentrations demands a powerful Raman lidar and significant signal accumulation time.

The lidar-derived mixing ratio of methane can be calculated from the ratio of CH₄ and N₂ lidar Raman signals (P_{CH_4} and P_{N_2}), corrected for the aerosol and molecular differential

extinction:

$$n_{\text{CH}_4}(z) = K \frac{P_{\text{CH}_4}}{P_{\text{N}_2}} \exp \left\{ - \int_0^z \left[\alpha_{\text{N}_2}^a \left(1 - \left(\frac{\lambda_{\text{CH}_4}}{\lambda_{\text{N}_2}} \right)^{-\gamma} \right) + \alpha_{\text{N}_2}^m \left(1 - \left(\frac{\lambda_{\text{CH}_4}}{\lambda_{\text{N}_2}} \right)^{-4} \right) \right] dz' \right\}. \quad (2)$$

Here λ_{N_2} and λ_{CH_4} are the wavelengths of nitrogen and methane Raman components; $\alpha_{\text{N}_2}^a$ and $\alpha_{\text{N}_2}^m$ are the aerosol and molecular extinctions at λ_{N_2} ; γ is the Ångström exponent and K is the calibration constant. In our measurements, we assume that the CH₄ mixing ratio above the boundary layer is 2 ppm and this value was used for calibration purposes. The calibration, in principle, can be performed from first principles by using a calibration lamp with a known spectrum, as has been done for Raman water vapor lidars (Venable et al., 2011). The methane mixing ratio in Eq. (2) is calculated from the ratio of the lidar signals, so the geometrical overlap factors are at least partially compensated and thus measurements below the height of the full overlap are possible. We still need to extrapolate the extinction coefficient to the region of incomplete overlap. However, the influence of the aerosol differential extinction term in Eq. (2) is lower than in the water vapor measurements due to the lower wavelength separation between nitrogen and methane Raman components.

To estimate the statistical uncertainties of methane detection, we assume that a uniform aerosol layer extends from the ground up to 2 km in height. In modeling the aerosol extinction coefficients at 355 nm, extinction values of 0.05, 0.1 and 0.2 km⁻¹ were considered. The number of detected photons was calculated from Eq. (1) for $\Delta z = 100$ m, $A_{\text{CH}_4} = 0.1$ and $n_{\text{CH}_4} = 2$ ppm. The assumed laser pulse energy was 70 mJ at 354.7 nm, which corresponds with the LILAS laser energy during the observations reported. The nitrogen Raman-scattering cross section of 5.4×10^{-31} cm² sr⁻¹ at 488 nm is taken from Penney et al. (1974) and recalculated for 355 nm. Finally, assuming that $\frac{\sigma_{\text{CH}_4}}{\sigma_{\text{N}_2}} = 8.2$ (Weber, 1979), the value $\sigma_{\text{CH}_4} = 1.9 \times 10^{-29}$ cm² sr⁻¹ at 355 nm was used. Statistical uncertainties of the measurements are determined mainly by the weak CH₄ Raman backscatter and, in the absence of background noise, the uncertainty can be estimated as $\varepsilon \approx \frac{1}{\sqrt{N_{\text{CH}_4}^{\text{ph}}}}$.

Figure 2 shows vertical profiles of statistical uncertainties for three values of the aerosol extinction coefficient: 0.05, 0.1, 0.2 km⁻¹ and a signal-averaging time of 4 h. The figure also shows the photon-counting rate in the methane Raman channel $\nu_{\text{CH}_4} = N_{\text{CH}_4}^{\text{ph}} \frac{2\Delta z}{c}$, where c is the speed of the light. For the clean atmosphere ($\alpha_{355} = 0.05$ km⁻¹) the measurements with uncertainty below 10% are possible up to 4 km, while for $\alpha_{355} = 0.2$ km⁻¹ the corresponding range decreases to 3 km. The simulation results confirm the necessity

Figure 2. Modeled photon-counting rate (lines) and statistical uncertainties of the methane mixing ratio measurements (lines and symbols) for a 2 ppm methane concentration and three values of aerosol extinction coefficient $\alpha_{355} = 0.05, 0.1, 0.2$ km⁻¹. Aerosol extends from $z = 0$ to $z = 2000$ m. Signal-averaging time is 4 h.

of long-term (several hours) signal accumulation in methane measurements using Raman lidar.

4 Results of measurements

Measurements were taken on the Lille University observatory platform, France, during the period May–June 2018. In total, 20 nighttime observation sessions were accomplished. Figure 3 shows CH₄ and N₂ Raman lidar signals together with the backscattered signal at 1064 nm on the night of 14–15 June 2018. The results are averaged over the temporal interval $\tau_{\text{av}} = 4.0$ h. Aerosols are mainly located below 1700 m (maximal value of aerosol extinction α_{355} inside the PBL is about 0.1 km⁻¹), though a weak aerosol layer is also visible in the 1064 nm lidar signal in the 2.5–4.0 km height interval. HYSPLIT back-trajectory analysis (Stein et al., 2015; Rolph et al., 2017) shows that the air mass in this layer originates from Canada, having been transported over the Atlantic. The photon-counting rate in the methane channel at 2000 m is about 1.8 KHz, which agrees with simulation results in Fig. 2 for $\alpha_{355} = 0.1$ km⁻¹. As mentioned, for a 2 ppm CH₄ mixing ratio, the nitrogen Raman backscatter should be approximately 6×10^4 stronger than that from methane. The value estimated from our measurements of 5×10^4 agrees well with this prediction, which confirms that we observed methane Raman scattering. The profile of the methane mixing ratio calculated from the measurements in Fig. 3 and averaged over 100 m height bins is shown in Fig. 4. The same figure provides the profile of the backscattering coefficient at

Figure 3. Lidar signals corresponding to elastic scattering at 1064 nm, nitrogen Raman scattering at 387 nm and methane Raman scattering at 396 nm on the night of 14–15 June 2018. The units are MHz for 387 and 396 nm, and mV for 1064 nm. Black lines show the profiles of molecular scattering. Measurements were taken from 22:00 to 02:00 UTC. Signal-averaging time $t_{\text{aver}} = 4.0$ h.

532 nm. The mixing ratio is given in arbitrary units, assuming that the value of 1.0 corresponds to $n_{\text{CH}_4} = 2$ ppm. The mixing ratio inside the PBL exceeds the corresponding values above 4000 m by approximately a factor of 2. The profiles of n_{CH_4} and β_{532} are not correlated: inside the PBL the maximum of β_{532} is at a height of 1500 m, while the maximum of n_{CH_4} is at 1100 m. The backscattering coefficient β_{532} of the weak aerosol layer at 3500 m is about $7.6 \times 10^{-5} \text{ km}^{-1} \text{ sr}^{-1}$, which is almost a factor of 50 lower than the maximum value of β_{532} inside the PBL. In this elevated layer, the CH₄ mixing ratio also increases; however n_{CH_4} at 3500 m is 1.5, which is close to the values in the PBL. Thus, the enhancement of n_{CH_4} at 3500 m is very unlikely to be an artifact related to aerosol interference.

The derived methane profiles exhibited strong night-to-night variation. Figure 5 shows the results of six measurement sessions, representing nights with different aerosol loadings. On the night of 20–21 May (Fig. 5a) a scattering layer with a peak value of $\beta_{532} = 0.09 \text{ km}^{-1} \text{ sr}^{-1}$ occurs in the 2500–3100 m height range. The low lidar ratio (below 20 sr) and low depolarization ratio (below 5 %) indicate that this layer is likely a water cloud. Strong cloud scattering demonstrates no influence on the mixing ratio, which is about 1.0 in the center of the cloud, proving that the interference filters provide sufficient rejection of elastic scattering. It should also be mentioned that the Raman band of the liquid water extends from 395 to 409 nm (Avila et al., 2004; Reichardt, 2014), so potentially it can be an interfering factor in the methane measurements. However, Fig. 5a does not reveal a noticeable effect of liquid water Raman scattering on the methane profile due to the narrowband fil-

Figure 4. Vertical profiles of aerosol backscattering coefficient at 532 nm and methane mixing ratio calculated from measurements on 14–15 June for the same temporal interval as in Fig. 3. Mixing ratio is uncalibrated and the value 1.0 corresponds to approximately 2 ppm.

ter in the CH₄ channel. Cloud layers also occurred on 26–27 and 27–28 May (Fig. 5b, c) at a height of approximately 4000 m with maximum values of backscattering coefficients of $\beta_{532} = 0.006$ and $0.02 \text{ km}^{-1} \text{ sr}^{-1}$. As in Fig. 5a, the presence of clouds does not influence the methane measurements. By contrast, the night of 12–13 June (Fig. 5f) was characterized by a low aerosol backscattering coefficient in the 500–4000 m range (β_{532} is below $2 \times 10^{-4} \text{ km}^{-1} \text{ sr}^{-1}$) and the mixing ratio shows no significant deviation from the 1.0 value in the whole height range.

The vertical variation of methane content was related to the PBL height, as can be concluded from a comparison of Fig. 5d and e. On 30–31 May the aerosol is confined below 2000 m, while on 2–3 June it is below 750 m. The n_{CH_4} decreases from 2.4 at 500 m to 1.0 at 2000 m in the first case, while in the second case the background level of 1.0 is observed for the heights above 750 m. On 2–3 June, the increase of the CH₄ mixing ratio at 3400 m correlates with a weak aerosol layer ($\beta_{532} < 10^{-4} \text{ km}^{-1} \text{ sr}^{-1}$) at the same height. It is interesting that a stronger aerosol layer at 2300 m is not accompanied by an increase in n_{CH_4} . The air masses in both layers were transported over the Atlantic from Canada and corresponding backward trajectories are close, so we are not able to make conclusions about the difference in the nature of these layers.

Enhancement of n_{CH_4} in weak elevated aerosol layers was observed several times during the campaign. In all cases the

Figure 5. Vertical profiles of the methane mixing ratio and aerosol backscattering at 532 nm for six nighttime measurement sessions: (a) 20–21 May, (b) 26–27 May, (c) 27–28 May, (d) 30–31 May, (e) 2–3 June and (f) 12–13 June 2018. Mixing ratios are not calibrated and the value 1.0 corresponds to approximately 2 ppm. Signal-averaging time τ_{av} is given in hours.

air mass was transported over the Atlantic. One such observation session was on the night of 13–14 June 2018. Figure 6 shows the temporal–spatial distribution of the range-corrected lidar signal at 1064 nm and the particle depolarization ratio at 532 nm for this session. Most of the aerosols are below 2000 m, but there is an elevated layer in the 3000–5000 m height range. The depolarization ratio inside the PBL is low ($\delta_{532} < 5\%$), while in the elevated layer δ_{532} increases up to approximately 18%. The available radiosonde data from Paris (France) and Essen (Belgium) show that the relative humidity in the elevated layer is below 40%. The profiles of aerosol backscattering coefficient β_{532} , particle depolarization δ_{532} and CH₄ mixing ratio on 13–14 June for the temporal interval of 22:00–02:00 UTC are given in Fig. 7. In the PBL the mixing ratio is about 2.0, and in the elevated

layer the n_{CH_4} also demonstrates an increase up to approximately 1.5.

To understand the origin of this elevated layer, a 10-day back-trajectory analysis was performed for the air mass over Lille, at 4000 m, on 14 June 2018 at 00:00 UTC, using the HYSPLIT model. According to the analysis, the air mass was transported from eastern Asia (Russia and China) to North America and then over the Atlantic Ocean to Europe. Large-scale boreal fire activities were detected near the border of Russia and China in early June; thus the air mass at 4000 m could have contained fire emissions. Figure 8a–d plot the transport pathway of the air mass overlaid with the CO columnar concentration maps on 3, 6, 9 and 12 June. The CO concentration is derived from AIRS Level 3 CO products (Teixeira, 2013). The propagation of the air mass is clearly

Figure 7. Aerosol backscattering coefficient β_{532} , particle depolarization δ_{532} and CH₄ mixing ratio on 13–14 June 2018 for the temporal interval 22:00–02:00 UTC. Values of δ_{532} are multiplied by a factor of 0.1. Mixing ratios are not calibrated and the value 1.0 corresponds to approximately 2 ppm.

coincident with the transport of CO plumes. Studies have shown that CO₂, CO and CH₄ are among the main products of boreal forest fires (Hao et al., 1993; Worden et al., 2013).

CO originating from boreal fires is positively correlated with CH₄ concentration; however, the CH₄ product of AIRS is not as mature as the CO product due to the low sensitivity to CH₄ in the lower troposphere, so CO is a favorable tracer of fire emissions. In Fig. 8a, intense CO plumes are detected at the origin of the trajectory, which is close to the fire activities. Hence, it is possible that the observed methane plume comes from fire emissions in eastern Asia. Aged smoke particles mixed with Asian dust particles could be the reason for the high particle depolarization ratio observed in the elevated layer.

5 Discussions and conclusion

The results presented here demonstrate the feasibility of profiling the background mixing ratios of methane in the lower troposphere using Raman lidar. The photon-counting rate in the methane Raman channel agrees with numerical simulation for typical aerosol loading and a background CH₄ mixing ratio of 2 ppm, which confirms that we observe the methane Raman scattering. In our measurements we always observed enhanced concentrations of the methane inside the PBL compared to aerosol-free regions; thus analysis of methane ground sources in northern France is in our upcoming plans.

Taking Raman measurements of CH₄ mixing ratio close to 2 ppm is a challenging task due to different potential interfering factors, such as leakage of the elastic signal into the Raman channel, contribution of liquid water Raman scattering and aerosol fluorescence. Measurements taken inside the clouds revealed no interference of elastic signal or Raman liquid water spectra. Estimation of aerosol fluorescence contributions is more difficult. The aerosol fluorescence at wavelengths above 440 nm was reported recently by Reichardt et al. (2017). For profiling, the authors had to integrate the fluorescence signal over the spectral range of approximately 80 nm. In our system the filter bandwidth is only 0.3 nm, so we expect the fluorescence contribution to be suppressed. The CH₄ profiles are not always correlated with aerosol backscattering, which corroborates the hypothesis that, in the PBL, not aerosol fluorescence but methane is measured. However, we cannot completely exclude the fluorescence contribution. To measure and correct for it, if necessary, in future measurements we plan to introduce an additional control channel close to 393 nm, where no strong Raman lines exist and only fluorescence can be detected (Reichardt, 2014). Furthermore, an additional filter will be used to increase the rejection in 450–480 nm spectral range.

One of the main problems in the measurements presented is the long signal accumulation time, which was about 4 h in our case. A more powerful laser is needed to improve the temporal resolution of the measurements. Today, compact diode pumped lasers, with pulse energies of 60 mJ at 355 nm and 200 Hz repetition rate have become widely avail-

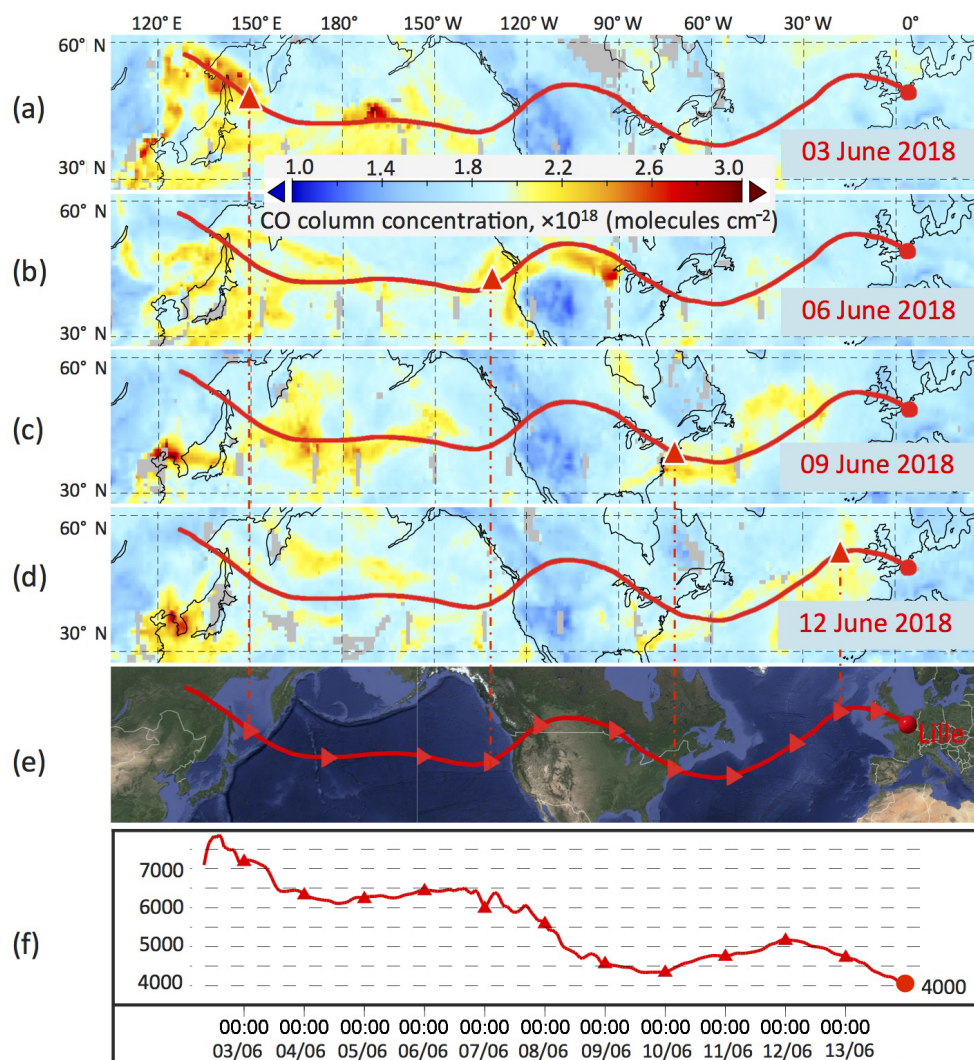

Figure 8. Ten-day backward trajectories for the air mass in Lille at an altitude of 4000 m on 14 June 2018 at 00:00 UTC. Panels (a)–(d) show the trajectory pathways overlaid with CO columnar concentration maps retrieved from AIRS data. The triangles represent the location of the traced air mass on corresponding dates. Panels (e) and (f) show the trajectory and vertical propagation of air mass.

able (e.g., <http://www.quantel-laser.com/en/products/item/q-smart-dpss-650-mj.html>, last access: 20 December 2018), so it is possible to decrease the measurement time to less than 30 min. Numerous lidar technologies developed previously for H₂O Raman systems can be used for the methane Raman lidar. In particular, the calibration technique based on the tungsten lamp spectrum can provide absolute values of methane mixing ratio from first principles (Venable et al., 2011).

Raman lidars for CH₄ monitoring cannot, of course, compete with airborne DIAL systems in sensitivity and accuracy, especially when column concentrations are considered. However, when one needs to evaluate the vertical profile of methane concentrations through the boundary layer, the Raman lidar may have some advantages. In particular, the IR DIALs can profile methane only in the region loaded with

aerosol, while Raman lidar is also capable of profiling in the aerosol-free atmosphere. Our results demonstrate that conventional Mie–Raman lidars designed for aerosol and the water vapor observations can be relatively easily modified for methane observations. Such ground-based lidars can be also used for ground validation activities during the upcoming MERLIN mission.

Data availability. Lidar measurements in Lille can be accessed under the following link: http://loa-ptfi.univ-lille1.fr/lidar/calendars/cal_2018_lillelilas.php (last access: 3 January 2019)

Competing interests. The authors declare that they have no conflict of interest.

Acknowledgements. The authors are very grateful to the labex CaPPA for supporting this study. The CaPPA project (Chemical and Physical Properties of the Atmosphere) is funded by the French National Research Agency (ANR) through the PIA (Programme d'Investissement d'Avenir) under contract "ANR-11-LABX-0005-01" and by the Regional Council "Nord-Pas de Calais" and the "European Funds for Regional Economic Development" (FEDER).
